Volume I

General Introduction 1

Pascal Richet, Reinhard Conradt and Akira Takada

- 1 A Historical Random Walk 2
- 2 Some Basic Concepts of Glass Science 7

Section I. Glassmaking 23

1.1 Glass Production: An Overview 25

Reinhard Conradt

- 1 Introduction 25
- 2 Industrially Manufactured Glasses 26
- 3 Process-controlling Properties 28
- 4 Glass Composition – its Relevance to Glass Properties 34
- 5 Perspectives 36

1.2 Raw Materials for Glassmaking: Properties and Constraints 39

Simonpietro Di Pierro

- 1 Introduction 39
- 2 Raw-material Specifications 40
- 3 From Raw Materials to Melt 45
- 4 Special Raw Materials 48
- 5 Perspectives 50

1.3 Fusion of Glass 53

Reinhard Conradt

- 1 Introduction 53
- 2 Overview of Industrial Processes 54
- 3 Batch Preparation 54
- 4 The Conversion of Batch into Melt 57
- 5 Fining, Refining, Homogenization 62
- 6 Energetics of Glass Melting 63
- 7 Perspectives 64

1.4 Primary Fabrication of Flat Glass 67

Toru Kamihori

- 1 Introduction 67
- 2 Overview 68
- 3 Updraw Processes 70
- 4 Roll Out Process 71
- 5 Float Process 72
- 6 Downdraw Processes 77
- 7 Perspectives 78

1.5 Fabrication of Glass Containers 81*Christian Roos*

- 1 Introduction 81
- 2 Principles of Glass-Container Forming 82
- 3 Glass-Container Forming Processes 84
- 4 Making of the Gob: Forehearth, Feeder, and Shears 87
- 5 IS-Forming Machine 88
- 6 Hot-End Handling, Hot-End Coating, and Annealing 91
- 7 Cold-End Handling and Inspection 91
- 8 Perspectives 92

1.6 Continuous Glass Fibers for Reinforcement 95*Hong Li and James C. Watson*

- 1 Introduction 95
- 2 Commercial Glass Fibers 95
- 3 Manufacturing of Glass Fibers 100
- 4 Markets and Applications 106
- 5 Perspectives 108

1.7 Simulation in Glass Processes 111*Patrick J. Prescott and Bruno Purnode*

- 1 Introduction 111
- 2 A Brief Overview 111
- 3 Fundamental Phenomena, Governing Equations, and Simulation Tools 113
- 4 Simulations in Glass Manufacturing Processes: A Few Examples 117
- 5 Simulation Data Management 123
- 6 Perspectives 125

Section II. Structure 127**2.1 Basic Concepts of Network Glass Structure 129***Alex C. Hannon*

- 1 Introduction 129
- 2 The Zachariasen–Warren Random Network Model 130
- 3 Silica – The Archetypal Glass 131
- 4 Microcrystalline Models 133
- 5 Modifiers and Non-Bridging Oxygens 133
- 6 Intermediate-Range Order 137
- 7 Chalcogenide Glasses 138
- 8 Perspectives 139

2.2 Structural Probes of Glass 141*Grant S. Henderson*

- 1 Introduction 141
- 2 Diffraction (Scattering) 143
- 3 X-ray Absorption Techniques 147
- 4 Nuclear Magnetic Resonance Spectroscopy 149
- 5 Vibrational Spectroscopies 151
- 6 Other Techniques 155
- 7 Perspectives 157

2.3 Microstructure Analysis of Glasses and Glass Ceramics 159*Christian Patzig and Thomas Höche*

- 1 Introduction 159
- 2 Scanning Electron Microscopy 160
- 3 Transmission Electron Microscopy 163
- 4 Scanning Probe Microscopy 168
- 5 X-Ray Microscopy 170
- 6 Perspectives 170

2.4	Short-range Structure and Order in Oxide Glasses	173
	<i>Jonathan F. Stebbins</i>	
1	Introduction	173
2	One-component Oxide Glass Formers	173
3	Modifying the Network: Silicates and Phosphates	175
4	Modifying the Network: Borates and Germanates	176
5	Network Cations in Aluminosilicates	177
6	Short-range Order and Modifier Cations	178
7	Interactions of Network Modifiers and Network Order/Disorder	178
8	Perspectives	180
2.5	The Extended Structure of Glass	183
	<i>George Neville Greaves</i>	
1	Introduction	183
2	Extended Structure of Glass: The Need for a Multiplicity of Techniques	185
3	Structural Order over Different Length Scales	187
4	Structural Aspects of Density Fluctuations	190
5	Models of Glass Structure	191
6	Structural Heterogeneity in Glasses	192
7	Perspectives	194
2.6	Structure of Chemically Complex Silicate Systems	197
	<i>Bjorn Mysen</i>	
1	Introduction	197
2	Glass and Melt Polymerization	197
3	Metal Oxide–SiO ₂ Systems	199
4	Aluminum and Aluminate	202
5	Ferric and Ferrous Iron	203
6	Minor Components in Silicate Glasses and Melts	205
7	Perspectives	205
2.7	Topological Constraint Theory of Inorganic Glasses	207
	<i>Prabhat K Gupta</i>	
1	Introduction	207
2	Concepts of the Topological Constraint Theory	208
3	Polyhedral Constraint Theory	210
4	The Bond Constraint Theory	212
5	Temperature-Dependent Constraints	214
6	Topological Constraint Theory, Thermodynamics, and the Potential Energy Landscape Formalism	217
7	Perspectives	218
2.8	Atomistic Simulations of Glass Structure and Properties	221
	<i>Akira Takada</i>	
1	Introduction	221
2	Basics of Numerical Simulations	222
3	Monte-Carlo Simulations	224
4	Molecular Dynamics Simulations	225
5	Modeling: Simulation Techniques and Examples	226
6	Perspectives	230
2.9	First-principles Simulations of Glass-formers	233
	<i>Walter Kob and Simona Ispas</i>	
1	Introduction	233
2	Ab Initio Simulations	234
3	Structural Properties	236
4	Vibrational Properties	238
5	Calculations of NMR Spectra	241
6	Perspectives	241

Section III. Physics of Glass 245**3.1 Glass Formation 249***Michael I. Ojovan*

- 1 Introduction 249
- 2 Glass and Relaxation 250
- 3 Kinetic Theory of Vitrification 250
- 4 The Viscosity Factor 252
- 5 Structural Factors 253
- 6 Glass-Liquid Transition 255
- 7 Perspectives 258

3.2 Thermodynamics of Glasses 261*Jean-Luc Garden and Hervé Guillo*

- 1 Introduction 261
- 2 Basics of Nonequilibrium Thermodynamics 261
- 3 Supercooled Liquids 263
- 4 Glass as a Nonequilibrium Substance 264
- 5 Nonequilibrium Thermodynamics of the Glass Transition 266
- 6 Physical Aging 269
- 7 Perspectives 270

3.3 The Glass Transition and the Entropy Crisis 273*Purushottam D. Gujrati*

- 1 Introduction 273
- 2 Important Concepts and Theories 273
- 3 Nonsingular Glass Phenomenology 277
- 4 Nonequilibrium Formulation: Brief Review 278
- 5 Nonequilibrium Relaxation in Internal Equilibrium 280
- 6 The Free Volume and the Communal Entropy 281
- 7 The Unifying Approach for Glasses 283
- 8 Perspectives 285

3.4 Atomic Vibrations in Glasses 287*Bernard Hehlen and Benoît Rufflé*

- 1 Introduction 287
- 2 Atomic Vibrations in Disordered Solids 288
- 3 Vibrations and Thermal Properties 289
- 4 Inelastic Spectroscopy in Glasses 291
- 5 Vibrational Spectra 292
- 6 The Boson Peak 296
- 7 Perspectives 298

3.5 Density of Amorphous Oxides 301*Michael J. Toplis*

- 1 Introduction 301
- 2 Measuring the Density of Amorphous Oxides 302
- 3 Measured Density Variations 305
- 4 Practical Applications 309
- 5 Perspectives 309

3.6 Thermodynamic Properties of Oxide Glasses and Liquids 313*Pascal Richet and Dominique de Ligny*

- 1 Introduction 313
- 2 Thermodynamic Functions 314
- 3 Low-temperature Heat Capacity and Entropy 318
- 4 High-temperature Properties 322

5	Reaction Thermodynamics	326
6	Perspectives	327
3.7	Structural and Stress Relaxation in Glass-Forming Liquids	331
	<i>Ulrich Fotheringham</i>	
1	Introduction	331
2	Structural Relaxation: A Few Examples	331
3	Structural Relaxation	332
4	Shear Viscoelasticity	339
5	Bulk Viscoelasticity	344
6	Perspectives	346
3.8	Hyperquenched Glasses: Relaxation and Properties	349
	<i>Yuanzheng Yue</i>	
1	Introduction	349
2	Fictive Temperature and Cooling Rates	349
3	Sub- T_g Relaxation	351
4	Anomalous Relaxation	352
5	Modeling of Sub- T_g Relaxation	353
6	Boson Peak	354
7	Resolving Glass Problems Via Hyperquenching-Annealing Calorimetry	354
8	Perspectives	357
3.9	Polyamorphism and Liquid-Liquid Phase Transitions	359
	<i>Paul F. McMillan and Martin C. Wilding</i>	
1	Introduction	359
2	Liquid-Liquid Phase Transitions and Polyamorphism	359
3	Classic Systems Exhibiting Polyamorphism	365
4	Perspectives	369
3.10	Pressure-Induced Amorphization	371
	<i>Paul F. McMillan, Denis Machon and Martin C. Wilding</i>	
1	Introduction	371
2	First Observation of PIA: Metastable Melting vs. Mechanical Destabilization of Ice Ih	371
3	SiO_2 and AlPO_4 : “Memory Glass” Effects	373
4	SnI_4 and Cu_2O : Examples of Compositionally Driven Instability	373
5	Nanocrystalline Materials	374
6	Zeolites as Examples of “Perfect Glass” Formation	375
7	Configurational Energy Landscapes	376
8	Perspectives	377
3.11	Mechanical Properties of Inorganic Glasses	379
	<i>Russell J. Hand</i>	
1	Introduction	379
2	The Importance of Flaws	379
3	Moduli and Hardness	380
4	Fracture Toughness and Strength	383
5	Flaws and Strength	385
6	Chemically Assisted Crack Growth – Stress Corrosion	387
7	Improving the Practical Strength of Glass	388
8	Perspectives	389
3.12	Strengthening of Oxide Glasses	391
	<i>K. Stefan R. Karlsson and Lothar Wondraczek</i>	
1	Introduction	391
2	Strength and Stresses	391
3	Elimination of Surface Flaws	393
4	Thermal Strengthening	395

- 5 Chemical Strengthening 398
- 6 Strengthening by Coating 401
- 7 Perspectives 402

3.13 Radiation Effects in Glass 405

Nadège Ollier, Sylvain Girard and Sylvain Peuget

- 1 Introduction 405
- 2 Point Defects 406
- 3 Vitreous Phase Stability and Bubble Formation 408
- 4 Glass Network Evolution Under Irradiation 408
- 5 Optical Properties 409
- 6 RIA and Emission 409
- 7 Effect on Mechanical Properties 411
- 8 Mitigation of Radiation Effects 412
- 9 Perspectives 412

3.14 Amorphous Ices 415

Robert F. Tournier

- 1 Introduction 415
- 2 Ice Phase Transitions 416
- 3 Predictions of Glass–Glass and Liquid–Liquid Transitions 418
- 4 Numerical Applications to Water 421
- 5 Supercluster Formation at the Glass Transition of Strong Liquids 426
- 6 Perspectives 426

Section IV. Transport Properties 429

4.1 Viscosity of Glass-Forming Melts 431

Joachim Deubener

- 1 Introduction 431
- 2 General Aspects and Definitions 432
- 3 Structural Aspects 433
- 4 Technological Aspects 434
- 5 Temperature Dependence of Viscosity 437
- 6 Composition Dependence 440
- 7 Dependence on Time and Strain Rate 444
- 8 Dependence on Microstructure 445
- 9 Perspectives 447

4.2 Ionic and Electronic Transport 453

Jean-Louis Souquet

- 1 Introduction 453
- 2 Ionic Conductivity and Diffusion 454
- 3 Ionic Transport Mechanisms 455
- 4 Ionic Transport Above the Glass Transition: An Entropic Mechanism 458
- 5 Electronically Conductive Glasses 459
- 6 Perspectives 462

4.3 Diffusion in Oxide Glass-forming Systems 465

Huaiwei Ni and Nico de Koker

- 1 Introduction 465
- 2 Physical and Chemical Description of Diffusion 465
- 3 Experimental Methods for Determining Diffusivity 467
- 4 Influence on Diffusivity of Species Properties 467
- 5 Compositional Control 470
- 6 Temperature and Pressure Effects 472
- 7 Insights from Molecular Dynamics Simulations 473
- 8 Perspectives 474

4.4 Chemical Diffusion in Multicomponent Glass-forming Systems 477*Mathieu Roskosz and Emmanuelle Guillard*

- 1 Introduction 477
- 2 Conceptual and Experimental Approaches 478
- 3 Tracer vs. Chemical Diffusion 479
- 4 Diffusion in Multicomponent Systems 480
- 5 Available Chemical Diffusion Data 482
- 6 Perspectives 484

4.5 Thermal Diffusivity and Conductivity of Glasses and Melts 487*Anne Hofmeister and Alan Whittington*

- 1 Introduction 487
- 2 Theory 487
- 3 Measurement Techniques 490
- 4 Thermal Diffusivity and Conductivity Data: Key Variables 493
- 5 Perspectives 499

4.6 Atomistic Simulations of Transport Properties 501*Junko Habasaki*

- 1 Introduction 501
- 2 MD Simulations: Conditions and Potentials 501
- 3 Dynamics 502
- 4 Insights into Dynamic Heterogeneities 505
- 5 Mixed Alkali Effect 508
- 6 Glass Transition and Thermodynamic Scaling 509
- 7 Perspectives 509

Section V. Chemistry of Glass 511**5.1 Chemical Analyses and Characterization of Glass 515***Thomas Bach, Reiner Haus and Sebastian Prinz*

- 1 Introduction 515
- 2 Gravimetry and Glass Digestion 517
- 3 X-Ray Fluorescence 517
- 4 Inductively Coupled Plasma Methods 518
- 5 Atomic Absorption Spectroscopy 520
- 6 Microprobe Analyses 521
- 7 Special Elements 521
- 8 Resistance to Chemical Attack 523
- 9 Analyses of Glass Defects 525
- 10 Perspectives 525

5.2 Phase Equilibria and Phase Diagrams in Oxide Systems 529*Ilya Veksler*

- 1 Introduction 529
- 2 Thermodynamic Principles 530
- 3 Basic Topological Types of Binary T - x Diagrams 532
- 4 Ternary Diagrams 537
- 5 Some Phase Diagrams for Glass-Forming Systems 538
- 6 Perspectives 541

5.3 Thermodynamic Models of Oxide Melts 545*Giulio Ottonello*

- 1 Introduction 545
- 2 General Considerations 546
- 3 Thermodynamic Models 548
- 4 First-Principles Calculations 555
- 5 Perspectives 556

5.4	Nucleation, Growth, and Crystallization in Inorganic Glasses	559
	<i>Edgar D. Zotto, Jörn W. P. Schmelzer and Vladimir M. Fokin</i>	
1	Introduction	559
2	Crystal Nucleation and Classical Nucleation Theory	560
3	Basic Models of Crystal Growth in Supercooled Liquids	564
4	Overall Crystallization and Glass-forming Ability: The Johnson–Mehl–Avrami–Kolmogorov Approach	565
5	Perspectives	567
5.5	Solubility of Volatiles	571
	<i>Bjorn Mysen</i>	
1	Introduction	571
2	Principles and Concepts	571
3	Reactive Volatiles in Silicate Glass and Melt	573
4	Nonreactive Volatiles in Silicate Glass and Melt	578
5	Perspectives	579
5.6	Redox Thermodynamics and Kinetics in Silicate Melts and Glasses	581
	<i>Reid F. Cooper</i>	
1	Introduction	581
2	Oxidation/Reduction Thermodynamics	581
3	Oxidation/Reduction Kinetics	586
4	Open-System Redox Dynamics	586
5	Closed-System (or Internal) Redox Dynamics	593
6	Perspectives	595
5.7	Optical Basicity: Theory and Application	597
	<i>John A. Duffy</i>	
1	Introduction: The Need for a Suitable Basicity Scale for Oxide Melts	597
2	Theoretical Foundation of Optical Basicity	597
3	Redox Equilibria in Network Melts	600
4	Optical Basicity and Electronic Polarizability	601
5	Chemical Reactions: Changes in Structure and Bonding	601
6	High and Low Optical–Basicity Materials	604
7	Optical Basicity and Electronegativity	604
8	Perspectives	606
5.8	The Glass Electrode and Electrode Properties of Glasses	609
	<i>Anatolii A. Belyustin and Irina S. Ivanovskaya</i>	
1	Introduction	609
2	Types and Properties of Glass Electrodes	610
3	Glass Structure as Viewed by the Glass Electrode	612
4	Theories of the Glass Electrode	614
5	Perspectives	616
5.9	Electrochemistry of Oxide Melts	619
	<i>Christian Rüssel</i>	
1	Introduction	619
2	Thermodynamics of Redox Equilibria	619
3	Experimental Aspects	620
4	Standard Potentials and Equilibrium Constants	621
5	Diffusion Coefficients	623
6	Voltammetric Sensors: Quantitative Determinations of Polyvalent Elements	624
7	Impedance Spectroscopy	625
8	Perspectives	626
5.10	Glass/Metal Interactions	629
	<i>Carine Petitjean, Pierre-Jean Panteix, Christophe Rapin, Michel Vilasi, Eric Schmucker and Renaud Podor</i>	
1	Introduction	629
2	Wetting, Sticking, and Adhesion Phenomena	629

- 3 Control of High-Temperature Chemical Interactions at the Metal/Molten Glass Interface 631
- 4 Characterization of the Glass/Metal Interaction 632
- 5 Corrosion of Metals and Alloys by Molten Glass 635
- 6 Perspectives 638

5.11 Durability of Commercial-type Glasses 639

Marie-Hélène Chopinet, Hervé Montigaud, Patrice Lehuédé and Sylvie Abensour

- 1 Introduction 639
- 2 Chemical Processes and Parameters 639
- 3 Alteration as Related to Glass Composition 641
- 4 Post-Production Corrosion of Flat and Container Glass 642
- 5 Characterization Methods 644
- 6 Protection Methods 645
- 7 Perspectives 645

5.12 Mechanisms of Glass Corrosion by Aqueous Solutions 647

Roland Hellmann

- 1 Introduction 647
- 2 Early Models 648
- 3 Leached-layer Model 648
- 4 Coupled Interfacial Dissolution-Reprecipitation (CIDR) 652
- 5 Rates of Dissolution and Element Release 657
- 6 Perspectives 660

Section VI. Glass and Light 663

6.1 Optical Glasses 665

Alix Clare

- 1 Introduction 665
- 2 Basic Features 666
- 3 Transmitted Light T_{in} 667
- 4 Glass Properties 670
- 5 Glass Responses 671
- 6 Interaction of Optical Components with Light 673
- 7 Perspectives 674

6.2 The Color of Glass 677

Georges Calas, Laurence Galois and Laurent Cormier

- 1 Introduction 677
- 2 Background on Color Processes 677
- 3 Crystal-Field-Driven Glass Color 681
- 4 Variation of Glass Coloration 685
- 5 Temperature Dependence of the Optical Absorption Spectra of Glasses: Thermochromism 687
- 6 Charge-Transfer Processes: From Amber Glasses to Lunar Glasses 688
- 7 Absorption by Organized Clusters and Nanophases 689
- 8 Perspectives 690

6.3 Photoluminescence in Glasses 693

Lothar Wondraczek

- 1 Introduction 693
- 2 Inelastic Light Scattering Through Photoluminescence 694
- 3 Photoluminescence and Glass Chemistry 697
- 4 Efficiency, Lifetime, and Quenching Effects 700
- 5 Applications 701
- 6 Perspectives 702

6.4 Optical Fibers 705

John Ballato

- 1 Introduction 705
- 2 Optical Properties and Fiber Designs 706

3	Optical Fiber Glasses	711
4	Optical Fiber Fabrication	714
5	Applications	718
6	Perspectives	718
6.5	Fluoride and Chalcogenide Glasses for Mid-infrared Optics	721
	<i>Bruno Bureau and Jacques Lucas</i>	
1	Introduction	721
2	Glass Transparency in the Infrared Region	721
3	Fluoride Glasses: Formation and Structure	723
4	Applications of Fluoride Glasses	724
5	Chalcogenide Glasses	726
6	Chalcogenide Glass Applications	730
7	Perspectives	732
6.6	Optoelectronics: Active Chalcogenide Glasses	735
	<i>Jong Heo and Kai Xu</i>	
1	Introduction	735
2	Active Chalcogenide Glasses Doped with Rare-Earth Ions	735
3	Optical Fiber Amplifiers	736
4	Mid-Infrared Lasers	739
5	Chalcogenide Quantum Dots	743
6	Perspectives	747
6.7	Modification Technologies of Glass Surfaces	751
	<i>İlkay Sökmen, Sener Oktik and Klaus Bange</i>	
1	Introduction	751
2	Hot-End Processes in Glass Production	752
3	Cleaning	754
4	Strengthening	756
5	Modification of the Surface Topography	757
6	Structuring and Texturing	757
7	Applications	758
8	Perspectives	760
6.8	Thin-Film Technologies for Glass Surfaces	763
	<i>Sener Oktik, İlkay Sökmen and Klaus Bange</i>	
1	Introduction	763
2	Deposition Techniques	764
3	Thin Films	766
4	Transparent Conducting Oxides	767
5	Miscellaneous Uses	772
6	Perspectives	772
6.9	Glass for Lighting	775
	<i>Hiroki Yamazaki and Shigeru Yamamoto</i>	
1	Introduction	775
2	Glass for Incandescent and Electric Discharge Lamps	776
3	Glass for Solid-State Lighting	781
4	Perspectives	784
6.10	Screens and Displays	787
	<i>Kei Maeda</i>	
1	Introduction	787
2	Cathode-Ray Tubes	788
3	Glasses for Flat-Panel Displays	790
4	Liquid-Crystal Displays	793
5	Plasma-Display Panels	794

- 6 Organic Light-Emitting Diodes 795
- 7 Device Configuration 795
- 8 Perspectives 796

Volume II

Section VII. Inorganic Glass Families 799

7.1 Extraterrestrial Glasses 801

Guy Libourel

- 1 Introduction 801
- 2 Chondrules: The Oldest Glasses of the Solar System 802
- 3 The Lunar Glass-Bead Factory 805
- 4 Cosmic Spherules 808
- 5 Terrestrial Versus Extraterrestrial 810
- 6 Perspectives 811

7.2 Geological Glasses 815

Cristina P. De Campos and Kai-Uwe Hess

- 1 Introduction 815
- 2 Compositional Diversity of Natural Glasses 815
- 3 Fulgurites: The Petrified Lightnings 817
- 4 Impact-Related Glasses 817
- 5 The Basalt Factory 820
- 6 Siliceous Glasses 822
- 7 The Fate of Natural Glasses 825
- 8 Compositional vs. Rheological Variability 826
- 9 Perspectives 828

7.3 Corrosion of Natural Glasses in Seawater 831

Roland Hellmann

- 1 Introduction 831
- 2 From Basalt Glass to Palagonite 831
- 3 Seafloor Basalt Alteration by Abiotic and Biotic Processes 832
- 4 Alteration Enhancement by Microorganism Metabolic Processes 832
- 5 Biotic Corrosion Models 833
- 6 Abiotic Corrosion Models 836
- 7 The Abiotic vs. Biotic Alteration Debate 838
- 8 Which Mechanism Controls Basalt Glass Corrosion? 839
- 9 Perspectives 840

7.4 Metallurgical Slags 843

Kenneth C. Mills

- 1 Introduction 843
- 2 Basic Constraints: A Summary 844
- 3 From Composition to Reactivity 846
- 4 Slag Properties 847
- 5 Transport Properties 849
- 6 Thermodynamic Properties 853
- 7 Perspectives 854

7.5 Water Glass 857

Hans Roggendorf

- 1 Introduction 857
- 2 Fabrication of Water Glass 857
- 3 Materials and Chemical Stability and Structure 859
- 4 Properties of Water Glass 863
- 5 Applications of Water Glass 863
- 6 Perspectives 864

7.6 Borosilicate Glasses 867*Randall E. Youngman*

- 1 Introduction 867
- 2 Borosilicate Applications 867
- 3 Vycor: A Composition–Structure Case Study 870
- 4 Structural Aspects 871
- 5 Temperature and Pressure Variations of Network Structure 874
- 6 Perspectives 876

7.7 Glass for Pharmaceutical Use 879*Daniele Zuccato and Emanuel Guadagnino*

- 1 Introduction 879
- 2 Glass Products and Types 879
- 3 Production of Pharmaceutical Glasses and Containers 880
- 4 Physical Resistance 882
- 5 Chemical Resistance 883
- 6 Surface Interactions with Pharmaceutical Products 885
- 7 Internal/External Treatments for Chemical/Mechanical Resistance 887
- 8 Perspectives 888

7.8 Oxynitride Glasses 891*Stuart Hampshire and Michael J. Pomeroy*

- 1 Introduction 891
- 2 Solubility of Nitrogen in Glasses 891
- 3 Glass Formation in M–Si–Al–O–N Systems and Its Representation 892
- 4 Structure of Oxynitride Glasses 893
- 5 Effects of Composition on Properties 895
- 6 Oxynitride Glass–Ceramics 898
- 7 Phosphorus Oxynitride Glasses 899
- 8 Lower-Temperature Preparation Methods 899
- 9 Perspectives 899

7.9 Phosphate Glasses 901*Andrew James Parsons*

- 1 Introduction 901
- 2 Structure 902
- 3 Synthesis 904
- 4 Physical Properties 906
- 5 Optical Properties 908
- 6 Chemical Properties 911
- 7 Other Applications 914
- 8 Perspectives 914

7.10 Bulk Metallic Glasses 919*Dmitri V. Louzguine-Luzgin and Akihisa Inoue*

- 1 Introduction 919
- 2 Glass Formation 920
- 3 Structure 923
- 4 Mechanical Properties 925
- 5 Deformation Behavior at Room Temperature 927
- 6 Magnetism: Properties and Applications 931
- 7 Other Properties and Applications 932
- 8 Perspectives 934

7.11 Glass-Ceramics 937*Monique Comte*

- 1 Introduction 937
- 2 History and Present Uses of Glass-Ceramics 937

- 3 Properties of Glass-Ceramics 943
- 4 Examples of Glass-Ceramics 945
- 5 Perspectives 949

Section VIII. Organically Related Glasses 951

8.1 Biogenic Silica Glasses 955

Jacques Livage and Pascal Jean Lopez

- 1 Introduction 955
- 2 A Slowly Awakening Scientific Interest 956
- 3 Biogenic Silica 958
- 4 The Low-Temperature Silica Factories 962
- 5 Biomimetism and Applications 963
- 6 Biogenic Silica in the Global Ecosystem 964
- 7 Perspectives 964

8.2 Sol–Gel Process and Products 969

Rui M. Almeida and M. Clara Gonçalves

- 1 Introduction 969
- 2 Sol–Gel Processing 970
- 3 Advantages and Drawbacks of the Sol–Gel Process 974
- 4 Sol–Gel Products and Applications 974
- 5 Perspectives 978

8.3 Silica Aerogels 981

Wim J. Malfait, Jannis Wernery, Shanyu Zhao, Samuel Brunner, and Matthias M. Koebel

- 1 Introduction 981
- 2 Synthesis 982
- 3 Properties 983
- 4 Applications 986
- 5 Markets and Industrial Production 986
- 6 Silica Hybrid Aerogels, Aerogel Composites, and Non-silica Aerogels 988
- 7 Perspectives 988

8.4 Bioactive Glasses 991

Delia S. Brauer and Julian R. Jones

- 1 Introduction 991
- 2 Melt-Derived Bioactive Glasses 991
- 3 Bioactive Sol–Gel Glasses 993
- 4 Degradation and Apatite Formation 994
- 5 Biological Response 996
- 6 Therapeutic Ions in Bioactive Glasses 997
- 7 Applications of Bioglasses 998
- 8 Perspectives 1001

8.5 Dental Glass-Ceramics 1005

Wolfram Höland and Marcel Schweiger

- 1 Introduction 1005
- 2 History and Present Uses of Dental Glass-Ceramics 1006
- 3 Properties of Dental Glass-Ceramics 1006
- 4 Examples of Dental Glass-Ceramics 1007
- 5 Perspectives 1010

8.6 Relaxation Processes in Molecular Liquids 1013

Thomas Blochowicz, Ernst A. Rössler and Michael Vogel

- 1 Introduction 1013
- 2 From the Boiling Point Down to the Glass Transition 1015
- 3 Binary Glass-Forming Liquids 1021
- 4 Secondary Relaxations 1024

5 Plastic and Glassy Crystals 1026

6 Perspectives 1027

8.7 Physics of Polymer Glasses 1031

Jean-Pierre Cohen-Addad

1 Introduction 1031

2 Polymeric Chains 1032

3 Polymeric Liquids 1033

4 Polymer Transformations 1036

5 Glass Transitions and Aging 1036

6 Polymer Products 1039

7 Perspectives 1040

8.8 Introduction to Polymer Chemistry 1043

Oliver Weichold

1 Introduction 1043

2 Polymer Synthesis 1045

3 Polymerization Processes 1050

4 The Solid State 1052

5 Perspectives 1054

8.9 Hybrid Inorganic–Organic Polymers 1057

Karl-Heinz Haas and Gerhard Schottner

1 Introduction 1057

2 Sol–Gel for Hybrid Materials 1057

3 Coatings 1061

4 Particles 1065

5 Bulk Materials, Fibers, and Composites 1065

6 Perspectives 1066

Section IX. Environmental and Other Issues 1069

9.1 Structural Glass in Architecture 1071

Freek Bos and Christian Louter

1 Introduction 1071

2 Scheme Design 1071

3 Float-Glass Processing for Structural Applications 1074

4 Design and Detailing 1077

5 Connections 1079

6 Perspectives 1083

9.2 Tempered and Laminated Glazing for Cars 1091

René Gy

1 Introduction 1091

2 A Brief History from the Early Twentieth Century to Today's Huge Market 1091

3 Glazing Functions 1092

4 Manufacturing 1097

5 Perspectives 1101

9.3 Stone and Glass Wool 1103

Yuanzheng Yue and Mette Solvang

1 Introduction 1103

2 Classification of Man-Made Vitreous Wool 1104

3 Fiber Spinning Technologies 1104

4 Melt Viscosity and Fiber Spinnability 1106

5 Physical Properties of Stone and Glass Wool 1108

6 Biopersistence and Biodurability 1110

7 Perspectives 1111

9.4 Glasses for Solar-energy Technologies 1113*Joachim Deubener and Gundula Helsch*

- 1 Introduction 1113
- 2 The Energy Problem 1113
- 3 Solar Electricity 1114
- 4 Solar Heat 1117
- 5 Solar Fuels 1120
- 6 Solar Water Treatments 1121
- 7 Perspectives 1122

9.5 Sulfide-glass Electrolytes for All-solid-state Batteries 1125*Akitoshi Hayashi and Masahiro Tatsumisago*

- 1 Introduction 1125
- 2 Classification of All-solid-state Batteries 1126
- 3 Sulfide Glasses 1127
- 4 Sulfide Glasses as Solid Electrolytes 1128
- 5 Bulk-type Batteries with Sulfide Electrolytes 1130
- 6 Interfacial Design 1131
- 7 Perspectives 1133

9.6 The World of the Flat-glass Industry: Key Milestones, Current Status, and Future Trends 1135*Bernard J. Savaète*

- 1 Introduction 1135
- 2 A Short Overview: Processes and Products 1135
- 3 The Float-glass World 1139
- 4 Perspectives 1145

9.7 Design and Operation of Glass Furnaces 1147*Christoph Jatzwauk*

- 1 Introduction 1147
- 2 The Furnace Families 1148
- 3 Melter 1152
- 4 Heat Management 1155
- 5 Furnace Design 1159
- 6 NO_x Emissions 1161
- 7 Perspectives 1162

9.8 Physics and Modeling of Glass Furnaces 1165*Reinhard Conradt and Erik Muijsenberg*

- 1 Introduction 1165
- 2 Furnace Parameters 1166
- 3 The Physics of Glass Furnaces 1166
- 4 Modeling of Glass Furnaces 1173
- 5 Perspectives 1176

9.9 Glass Cullet: Sources, Uses, and Environmental Benefits 1179*Nicola Favaro and Stefano Ceola*

- 1 Introduction 1179
- 2 Basic Features of Cullet 1180
- 3 Glass Recycling 1182
- 4 Separation Technologies 1184
- 5 Miscellaneous 1186
- 6 Environmental Aspects 1187
- 7 Perspectives 1188

9.10 Immobilization of Municipal and Industrial Waste 1191*Soraya Heuss-Aßbichler and Athanasius P. Bayuseno*

- 1 Introduction 1191

2	Municipal Solid Waste Incineration Residues	1192
3	Environmental Impact of MSWI Residues	1199
4	Special Residues	1201
5	Perspectives	1203
9.11	Nuclear Waste Vitrification	1205
	<i>Olivier Pinet, Etienne Vernaz, Christian Ladirat, and Stéphane Gin</i>

11.1 Postface – A Personal Retrospective 1457

C. Austen Angell

Subject Index 1463

Name Index 1489

List of Contributors

Functions and affiliations at the time of publication of the *Encyclopedia*

Abensour, Sylvie

Analytical Chemistry Group Manager
Expertise Department on Crystalline and Composite Materials,
Saint-Gobain Research Paris
39 Quai Lucien Lefranc, 93300 Aubervilliers, France
– 5.11: Durability of Commercial-type Glasses.

Almeida, Rui M.

Catedrático, Departamento de Engenharia Química, CQE
Instituto Superior Técnico
Universidade de Lisboa
Av. Rovisco Pais 1049-001 Lisboa, Portugal
– 8.2: Sol-gel Processes and Products.

Angell, C. Austen

Regent's Professor, School of Molecular Sciences
Arizona State University Tempe, AZ 85287-1604, USA
– 11.1: Postface – A Personal Retrospective.

Bach, Thomas

Head of Laboratory, Dorfner Analysenzentrum und
Anlagenplanungsgesellschaft mbH (ANZAPLAN)
Scharhof 1, 92242 Hirschau, Germany
– 5.1: Chemical Analyses and Characterization of Glass.

Ballato, John, J. E.

Sirrine Endowed Chair in Optical Fiber, and Professor
Department of Materials Science and Engineering and the Center
for Optical Materials Science and Engineering Technologies
(COMSET)
Clemson University, Clemson SC 29631, USA
– 6.4: Optical Fibers.

Bange, Klaus

Consultant, MK Consulting GmbH, Burgunderstr. 8, 55270
Jugenheim, Germany
– 6.7: Modification Technologies of Glass Surfaces;
6.8: Thin-Film Technologies for Glass Surfaces.

Bayuseno, Athanasius P.

Professor, Centre for the Waste Management
Department of Mechanical Engineering
Diponegoro University, Tembalang Campus Semarang 50275,
Indonesia
– 9.10: Immobilization of Municipal and Industrial Waste.

Belyustin, Anatolii A. (deceased)

Former Professor of Physical Chemistry, Chemistry Institute c/o
Saint Petersburg State University Physical Chemistry Department,
Saint Petersburg State University, Universitetskii prospect, 26,
Petrodvorets
198504 Saint Petersburg, Russia
– 5.8: The Glass Electrode and Electrode Properties
of Glasses.

Beretta, Marco

Professor of History of Science
Dipartimento di Filosofia e Comunicazione
Università di Bologna, via Zamboni 38, 40126 Bologna, Italy
– 10.4: Glass and the Philosophy of Matter in Antiquity.

Blochowicz, Thomas

Privatdozent, Institut für Festkörperphysik
Technische Universität Darmstadt, Hochschulstraße 6-8
64289 Darmstadt, Germany
– 8.6: Relaxation Processes in Molecular Liquids.

Bos, Freek

Assistant Professor Concrete Structures
Unit Structural Design, Department of the Built Environment,
Eindhoven University of Technology (TU/e), PO Box 513, 5600 MB
Eindhoven
The Netherlands
– 9.1: Structural Glass in Architecture.

Brauer, Delia S.

Professor for Bioactive Glasses
Otto Schott Institute of Materials Research
Friedrich Schiller University Jena
Fraunhoferstr. 6, 07743 Jena, Germany
– 8.4: Bioactive Glasses.

Brunner, Samuel

Research Scientist, Laboratory for Building Energy Materials and
Components, EMPA
Überlandstrasse 129, 8600 Dübendorf Switzerland
– 8.3: Silica Aerogels.

Bureau, Bruno

Professor, Université de Rennes I, Verres et Céramiques
Institut des Sciences Chimiques, UMR-CNRS 6226
35700 Rennes, France
– 6.5: Fluoride and Chalcogenide Glasses for
Mid-infrared Optics.

Calas, Georges

Professor, Institut de Mineralogie, de Physique des Matériaux et de Cosmochimie, Sorbonne Université
UMR CNRS 7590, Muséum National d'Histoire Naturelle, IRD, 4
Place Jussieu 75005 Paris, France
– 6.2: The Color of Glass.

Ceola, Stefano

Researcher, Stazione Sperimentale del Vetro
Via Briati 10, 30141 Venice, Italy
– 9.9: Glass Cullet: Sources, Uses, and Environmental Benefits.

Chopinnet, Marie-Hélène

Former Senior Research Engineer
Saint-Gobain Research Paris, 90 rue Duhesme
75018 Paris, France
– 5.11: Durability of Commercial-type Glasses; 10.9: Furnaces and Glassmaking Processes: From Ancient Tradition to Modernity.

Clare, Alix

Professor, Kazuo Inamori School of Engineering
Alfred University, Alfred, NY 14802, USA
– 6.1: Optical Glasses.
Cohen-Addad, Jean-Pierre (deceased)
Former Professor, Laboratoire LiPhy
Université J. Fourier, Grenoble
38402 Saint-Martin d'Hères, France
– 8.7: Physics of Polymer Glasses.

Colomban, Philippe

Emeritus Research Director, CNRS
Laboratory "From Molecule to Nano-object: Reactivity,
Interaction & Spectroscopies," Sorbonne Universités, 4 place
Jussieu, 75252 Paris Cedex 05, France
– 10.6: Glazes and Enamels.

Comte, Monique

Research Engineer, Advanced Materials Research Group, Corning
European Technology Center
Corning SAS, 77210 Avon, France
– 7.11: Glass-Ceramics.

Conradt, Reinhard

Uniglass AC GmbH, Nizzaallee 75
52072 Aachen, Germany, President
Deutsche Glastechnische Gesellschaft
Former Professor of Glass and Ceramic Composites
RWTH Aachen University, Aachen 52072, Germany
– General Introduction; 1.1: Glass Production: An Overview; 1.3:
Fusion of Glass; 9.8: Physics and Modeling of Glass Furnaces.

Cooper, Reid F.

Professor, Department of Earth, Environmental and Planetary
Sciences, Brown University, Box 1946, Providence RI 02912, USA
– 5.6: Redox Thermodynamics and Kinetics in Silicate
Melts and Glasses.

Cormier, Laurent

Research Director, Institut de Mineralogie
de Physique des Matériaux et de Cosmochimie
Sorbonne Université, UMR CNRS 7590, Muséum National
d'Histoire Naturelle, IRD, 4 Place Jussieu
75005 Paris, France
– 6.2: The Color of Glass.

de Campos, Cristina P., Visiting Professor
Earth and Environmental Sciences
Ludwig-Maximilians-Universität LMU
Theresienstr. 41/III Munich 80333, Germany
– 7.2: Geological Glasses.

Degryse, Patrick

Professor, Department of Earth and Environmental Sciences –
Geology, Center for Archaeological Sciences
KU Leuven, Celestijnenlaan 200E
Box 2408, BE-3001, Leuven
Belgium and Faculty of Archaeology
Universiteit Leiden, Leiden
the Netherlands
– 10.2: Ancient Glass Late Bronze Age.

de Koker, Nico

Research Fellow, Department of Civil Engineering
University of Stellenbosch, 7600, South Africa
– 4.3: Diffusion in Oxide Glass-forming Systems.

de Ligny, Dominique

Chair of Glass and Ceramics
Department of Materials Science and Engineering
Friedrich Alexander Universität Erlangen-Nürnberg
Martensstr. 5, 91058 Erlangen, Germany
– 3.6: Thermodynamic Properties of Oxide Glasses and Liquids.

Deubener, Joachim

Professor of Glass Science and Engineering
Institute of Non-Metallic Materials
Clausthal University of Technology
38678 Clausthal-Zellerfeld, Germany
– 4.1: Viscosity of Glass-forming Melts;
9.4: Glass for Solar-energy Technologies.

Di Piero, Simonpietro

Director, Expertise Department on Crystalline and Composite
Materials, Saint-Gobain Research Paris
39 Quai Lucien Lefranc
93300 Aubervilliers, France
– 1.2: Raw Materials for Glass Making: Properties and Constraints.

Duffy, John A. (deceased)

Former Emeritus Professor of Chemistry
University of Aberdeen, Old Aberdeen
AB24 3UE Scotland, UK
– 5.7: Optical Basicity: Theory and Application.

Dyon, Joël

Designer and Project Manager
Institut de Physique du Globe de Paris
1 rue Jussieu, 75005 Paris, France.

Favaro, Nicola

Laboratory Director, Stazione Sperimentale del Vetro
Via Briati 10, 30141 Venice, Italy
– 9.9: Glass Cullet: Sources Uses, and Environmental Benefits.

Fokin, Vladimir M.

Senior Research Fellow
Vavilov State Optical Institute
ul. Babushkina 36-1, 193 171 Saint Petersburg, Russia
– 5.4: Nucleation, Growth, and Crystallization in Inorganic Glasses.

Fotheringham, Ulrich

Senior Principal Scientist
Central Research and Technology Development
Schott AG, 55014 Mainz, Germany
– 3.7: Structural Shear, and Stress Relaxation in Glass-forming Liquids.

Freestone, Ian, C.

Professor, Institute of Archaeology,
University College London
31–34 Gordon Square, London WC1H 0PY, UK
– 10.3: Roman Glass.

Galoisy, Laurence

Maître de conférences, Institut de Mineralogie
de Physique des Matériaux et de Cosmochimie
Sorbonne Université, UMR CNRS 7590
Muséum National d'Histoire Naturelle, IRD
4 Place Jussieu, 75005 Paris, France
– 6.2: The Color of Glass.

Garden, Jean-Luc

R&D Engineer, CNRS, Institut Néel and Université de Grenoble
Alpes, F-38042 Grenoble, France
– 3.2: Thermodynamics of Glasses.

Gin, Stéphane

Research Director, CEA DEN/DTCD Marcoule
30207 Bagnols sur Cèze, France
– 9.11: Nuclear Waste Vitrification.

Girard, Sylvain

Professor, Laboratoire Hubert Curien, Univ Lyon
UJM Saint-Etienne, CNRS, IOGS, UMR 5516
18 rue du professeur Benoît Luras
42000 Saint-Etienne, France
– 3.13: Radiation Effects in Glass.

Gonçalves, M. Clara

Professora auxiliar, Departamento de Engenharia Química, CQE,
Instituto Superior Técnico
Universidade de Lisboa
Av. Rovisco Pais 1049-001 Lisboa, Portugal
– 8.2: Sol-gel Processes and Products.

Gouillart, Emmanuelle

Director, CNRS-Saint-Gobain Laboratory of Glass Surface and
Interfaces, Saint-Gobain Research Paris
39 quai Lucien Lefranc, 93303 Aubervilliers cedex, France
– 4.4: Chemical Diffusion in Multicomponent Glass-forming Systems.

Greaves, Neville G. (deceased)

Distinguished Research Fellow
Department of Materials Science and Metallurgy
University of Cambridge, Cambridge CB3 0FS, UK
– 2.5: The Extended Structure of Glass.

Guadagnino, Emanuel

European Pharmacopeia Expert, Italian Delegate
via Paolo Erizzo 20, Venezia (Ve) 30126, Italy
– 7.7: Glass for Pharmaceutical Use.

Guillou, Hervé

Maître de conférences, CNRS
Institut Néel and Université de Grenoble Alpes
38042 Grenoble, France
– 3.2: Thermodynamics of Glasses.

Gujrati, Purushottam D.

Professor, Department of Physics
Department of Polymer Science
The University of Akron, Akron
OH 44325, USA
– 3.3: The Glass Transition and the Entropy Crisis.

Gupta, Prabhat K.

Emeritus Professor, Department of Materials
Science and Engineering
The Ohio State University, Columbus OH 43235, USA
– 2.7: Topological Constraint Theory of Inorganic Glasses.

Gy, René

Department Manager, Thermomechanics & Modelling
Saint-Gobain Research Paris, 39 Quai Lucien Lefranc
93302 Aubervilliers, France
– 9.2: Tempered and Laminated Glazing for Cars.

Haas, Karl-Heinz

Research Scientist, Fraunhofer-Institut für Silicatforschung,
Neunerplatz 2, D-97082 Würzburg
Germany
– 8.9: Hybrid Inorganic–Organic Polymers.

Habasaki, Junko

Assistant Professor, School of Materials and Chemical Technology,
Tokyo Institute of Technology
4259 Nagatsuta-chi, Yokohama, Kanagawa 226-8502
Japan
– 4.6: Atomistic Simulations of Transport Properties.

Hampshire, Stuart

Emeritus Professor of Materials Science
Materials and Surface Science Institute
University of Limerick, Limerick V94 T19PX, Ireland
– 7.8: Oxynitride Glasses.

Hand, Russell J.

Professor of Glass Science & Engineering
Department of Materials Science & Engineering
University of Sheffield, Sir Robert Hadfield Building
Mappin Street, Sheffield S1 3JD, UK
– 3.11: Mechanical Properties of Inorganic Glasses.

Hannon, Alex C.

Research Scientist, ISIS Facility
R3, Rutherford Appleton Laboratory
Chilton, Didcot, Oxon OX11 0QX, UK
– 2.1: Basic Concepts of Network Glass Structure.

Haus, Reiner

Managing Director, Dorfner Analysenzentrum und
Anlagenplanungsgesellschaft mbH (ANZAPLAN), Scharhof 1,
92242 Hirschau, Germany
– 5.1: Chemical Analyses and Characterization of Glass.

Hayashi, Akitoshi

Professor, Department of Applied Chemistry
Faculty of Engineering, Osaka Prefecture University
1-1 Gakuen-cho, Naka-ku, Sakai
Osaka 599-8531, Japan
– 9.5: Sulfide Glass Electrolytes for All-solid-state Batteries.

Hehlen, Bernard

Professor, Laboratoire Charles Coulomb, UMR 5221 CNRS,
Université de Montpellier, 34095 Montpellier, France
– 3.4: Atomic Vibrations in Glasses.

Hellmann, Roland

Senior Scientist, ISTerre- Geochemistry Group
CNRS, Université Grenoble Alpes
38058 Grenoble Cedex 9, France
– 5.12: Mechanisms of Glass Corrosion by Aqueous Solutions;
7.3: Corrosion of Natural Glasses in Seawater.

Helsch, Gundula

Senior Scientist, Institute of Non-Metallic Materials, Clausthal
University of Technology
Zehnterstraße 2a, 38678 Clausthal-Zellerfeld, Germany
– 9.4: Glass for Solar-energy Technologies.

Henderson, Grant S.

Professor, Department of Earth Sciences,
University of Toronto
22 Russell St., Toronto, Ontario M5S 3B1, Canada
– 2.2: Structural Probes of Glass.

Heo, Jong

Professor, Department of Materials Science and Engineering
Pohang University of Science and Technology (POSTECH),
Gyeongbuk 790784,
Republic of Korea
– 6.6: Optoelectronics: Active Chalcogenide Glasses.

Hess, Kai-Uwe

Academic Staff, Department for Earth and Environmental Science,
Ludwig-Maximilians Universität München, Theresienstr. 41/III,
80333 Munich, Germany
– 7.2: Geological Glasses.

Heuss-Aßbichler, Soraya

Professor, Section of Mineralogy
Petrology and Geochemistry
Department for Earth and Environmental Science
Ludwig-Maximilians Universität München
Theresienstr. 41/III, 80333 Munich, Germany
– 9.10: Immobilization of Municipal and Industrial Waste.

Höche, Thomas

Head of the Optical Materials and Technologies Department,
Fraunhofer Institute for Microstructure of Materials and Systems
IMWS
Walter-Huelse-Strasse 1, D-06120 Halle (Saale), Germany
– 2.3: Microstructure Analysis of Glasses and Glass Ceramics.

Hofmeister, Anne

Research Professor, Department of Earth and Planetary Sciences
Washington University, St. Louis, MO 63130, USA
– 4.5: Thermal Diffusivity and Conductivity of Glasses and Melts.

Höland, Wolfram

Former Head of Fundamental Research on Glass and Ceramics,
Ivoclar Vivadent AG, R&D, Bendererstr. 2, 9494 Schaan,
Principality of Liechtenstein
– 8.5: Dental Glass Ceramics.

Inoue, Akihisa

Professor, International Institute of Green Materials, Josai
International University, Togane 283-8555, Japan; School of
Materials Science and Engineering
Tianjin University, Tianjin 300072, China;
Department of Physics, King Abdulaziz University, Jeddah 22254,
Saudi Arabia; National University of Science and Technology
(MISIS), Leninsky prosp. 4
Moscow 119049, Russia
– 7.10: Bulk Metallic Glasses.

Ispas, Simona

Maître de conférences, Laboratoire Charles Coulomb
Université de Montpellier, CNRS, 34095
Montpellier France
– 2.9: First-principles Simulations of Glass Formers.

Ivanovskaya, Irina, S.

Former Senior Researcher, Chemistry Institute c/o Saint Petersburg
State University Physical Chemistry Department, Saint Petersburg
State University
Universitetskii prospect, 26, Petrodvorets
198504 Saint Petersburg, Russia
– 5.8: The Glass Electrode and Electrode Properties of Glasses.

Jatzwauk, Christoph

Managing Director F.I.C. Germany GmbH
Eichenstraße 51, 92637 Weiden, Germany
– 9.7: Design and Operation of Glass Furnaces.

Jones, Julian R.

Professor of Biomaterials, Department of Materials, Imperial
College London, Exhibition Road, London SW7 2AZ, UK
– 8.4: Bioactive Glasses.

Kamihori, Toru

Deputy General Manager, Director, Glass Process Division, AGC
Inc., Innovative Technology Laboratories
Technology General Division, 1-1 Suehiro-cho
Tsurumi-ku, Yokohama-shi Kanagawa 230-0045, Japan
– 1.4: Primary Fabrication of Flat Glass.

Karlsson, K. Stefan R.

Senior Scientist, RISE Glass (Former Glafo)
Division of Built Environment, RISE Research Institutes of Sweden,
SE-351 96 Växjö, Sweden
– 3.12: Strengthening of Oxide Glasses.

Kob, Walter

Professor, Laboratoire Charles Coulomb, Université de Montpellier
CNRS, 34095 Montpellier, France
– 2.9: First-principles Simulations of Glass Formers.

Koebel, Mathias M.

Head, Laboratory for Building Energy Materials and Components,
EMPA, Überlandstrasse 129
8600 Dübendorf, Switzerland
– 8.3: Silica Aerogels.

Ladirat, Christian

Deputy Manager of Waste Containment and Vitrification Service,
Commissariat à l'Énergie Atomique
DEN/DTCD Marcoule, 30207 Bagnols sur Cèze, France
– 9.11: Nuclear Waste Vitrification.

Lehuédé, Patrice

Free Researcher, Centre de Recherche et Restauration des Musées
de France, 14, quai François Mitterrand
75001 Paris, France
– 5.11: Durability of Commercial-type Glasses.

Li, Hong

Senior Scientist, Nippon Electric Glass US, Fiber Glass Science &
Technology, PPG Industries, 940 Washburn Switch Rd., Shelby, NC
28150-9089, USA
– 1.6: Continuous Glass Fibers for Reinforcement.

Libourel, Guy

Professor, Université Côte d'Azur, Observatoire de la Côte d'Azur
CNRS, UMR 7293 Lagrange, Boulevard de l'Observatoire
CS34229, 06304 Nice Cedex 4, France
– 7.1: Extraterrestrial Glasses.

Livage, Jacques

Emeritus Professor, Collège de France and French Academy of
Sciences
Laboratoire de Chimie de la Matière Condensée de
Paris CNRS, UMR-7574, 4 place Jussieu, 75252 Paris Cedex 05
France
– 8.1: Biogenic Silica Glasses.

Lopez, Pascal Jean

Research Director and Director of the Observatoire Hommes-
Milieux Port Caraïbe, Biologie des Organismes Aquatiques et
Écosystèmes (BOREA), UMR CNRS 7208
Muséum National d'Histoire Naturelle, Sorbonne Université; IRD-
207 Université Caen Normandie; and Université des Antilles, 75005
Paris, France
– 8.1: Biogenic Silica Glasses.

Louter, Christian

Professor of Building Construction
Institute of Building Construction
Faculty of Civil Engineering
Technische Universität Dresden
01062 Dresden, Germany
– 9.1: Structural Glass in Architecture.

Louzguine-Luzgin, Dmitri V.

Professor, Principal Investigator, Laboratory Director, WPI
Advanced Institute for Materials Research and AIST-Tohoku
Mathematics for Advanced Materials – Open Innovation
Laboratory, Tohoku University
Aoba-Ku, Sendai 980-8577, Japan
– 7.10: Bulk Metallic Glasses.

Lucas, Jacques

Emeritus Professor, French Academy of Sciences, Université de
Rennes I
Verres et Céramiques, Institut des Sciences Chimiques
UMR-CNRS 6226, 35700 Rennes, France
– 6.5: Fluoride and Chalcogenide Glasses for Mid-infrared Optics.

Machon, Denis

Maître de conférences, Institut Lumière Matière
Université Claude Bernard Lyon 1, 10 rue Ada Byron
69622 Villeurbanne Cedex, France
– 3.10: Pressure-Induced Amorphization.

McMillan, Paul F.

Sir William Ramsay Professor of Chemistry
Christopher Ingold Laboratory, Department of Chemistry,
University College London, 20 Gordon Street
London WC1H 0AJ, UK
– 3.9: Polyamorphism and Liquid-Liquid Phase Transitions; 3.10:
Pressure-Induced Amorphization.

Maeda, Kei

Fellow, Asahi Glass Company Inc.
Research Center, 1150 Hazawa-cho, Kanagawaku
Yokohama 221-8755, Japan
– 6.10: Screens and Displays.

Malfait, Wim J.

Group Leader Superinsulation Materials, Laboratory for Building
Energy Materials and Components, EMPA
Überlandstrasse 129, 8600 Dübendorf, Switzerland
– 8.3: Silica Aerogels.

Martlew, David (deceased)

Glass Technologist, 15 Cecil Drive, Eccleston,
St Helens, UK
– 10.8: Stained Glass Windows.

Mills, Kenneth C. (deceased)

Former Professor, Department of Materials
Imperial College, London SW7 2AZ, England, UK
– 7.4: Metallurgical Slags.

Montigaud, Hervé

R&D Engineer, Associate Researcher
Surface du Verre et Interfaces
Saint-Gobain Research Paris, UMR 125 CNRS
39 Quai Lucien Lefranc, 93303 Aubervilliers Cedex, France
– 5.11: Durability of Commercial-type Glasses.

Muijsenber, Erik

Vice-president, Glass Service a.s
Rokytnice 60, 75501 Vsetin, Czech Republic
– 9.8: Physics and Modeling of Glass Furnaces.

Mysen, Bjorn

Senior Staff Member, Geophysical Laboratory
Carnegie Institution for Science, 5251 Broad Branch Rd
Washington, DC 20015, USA
– 2.6: Structure of Chemically Complex Silicate Systems; 5.5:
Solubility of Volatiles.

Ni, Huaiwei

Professor of Geochemistry, CAS Key Laboratory of Crust-Mantle
Materials and Environments School of Earth and Space Sciences,
University of Science and Technology of China, Hefei 230026,
China
– 4.3: Diffusion in Oxide Glass-forming Systems.

Ojovan, Michael I.

Professor, Department of Materials, Imperial College London
London SW7 2AZ, UK
– 3.1: Glass Formation.

Oktik, Sener

Chief Technology Officer, Türkiye Şişe ve Cam Fabrikaları A.Ş.,
Science and Technology Center
Cumhuriyet Mah. Şişecam Yolu Sok. No:2 41400 Gebze-Kocaeli,
Turkey
– 6.7: Modification Technologies of Glass Surfaces; 6.8: Thin-Film
Technologies for Glass Surfaces.

Ollier, Nadège

Research Scientist, Laboratoire des Solides Irradiés
Ecole polytechnique, CNRS, CEA, 91128 Palaiseau Cedex, France
– 3.13: Radiation Effects in Glass.

Ottonello, Giulio

Former Chair of Geochemistry, Laboratorio di Geochimica at
DISTAV, University of Genoa
Corso Europa 26: 16132 Genova, Italy
– 5.3: Thermodynamic Models of Oxide Melts.

Panteix, Pierre-Jean

Research Engineer, CNRS, Institut Jean Lamour UMR 7198;
Campus ARTEM, 2 allée André Guinier
BP 50840, 54011 Nancy Cedex, France
– 5.10: Glass/Metal Interactions.

Parker, John M.

MA (Cantab), FSGT, FIMMM, CEng
Professor Emeritus
Department of Materials Science and Engineering
Sheffield University
Sir Robert Hadfield Building, Mappin Street
Sheffield S10 5TX, UK
– 9.12: The International Commission on Glass (ICG); 10.8: Stained
Glass Windows.

Parsons, Andrew James

Senior Research Fellow, Faculty of Engineering
University of Nottingham, University Park
Nottingham NG7 2RD, UK
– 7.9: Phosphate Glasses.

Patzig, Christian

Senior Research Scientist, Fraunhofer Institute for Microstructure
of Materials and Systems IMWS
Walter-Huelse-Strasse 1, D-06120 Halle (Saale), Germany
– 2.3: Microstructure Analysis of Glasses and Glass Ceramics.

Petitjean, Carine

Maitre de conférences, Université de Lorraine
Institut Jean Lamour UMR 7198, Campus ARTEM, 2 Allée André
Guinier, BP 50840, 54011 Nancy Cedex, France
– 5.10: Glass/Metal Interactions.

Peuget, Sylvain

Senior Research Scientist, Commissariat à l'Énergie Atomique,
Nuclear Energy Division, BP 17171, 30207 Bagnols-sur-Cèze Cedex,
France
– 3.13: Radiation Effects in Glass.

Pinet, Olivier

Head of Research Laboratory for the Development of Conditioning
Matrices, Commissariat à l'Énergie Atomique, DEN/DTCD
Marcoule, 30207 Bagnols sur Cèze, France
– 9.11: Nuclear Waste Vitrification.

Podor, Renaud

Research Engineer CNRS, Institut de Chimie Séparative de
Marcoule, UMR 5257; Bât. 426, BP 17171, 30207 Bagnols sur Cèze
Cédex, France
– 5.10: Glass/Metal Interactions.

Pomeroy, Michael J.

Professor, Materials Science and Technology, Materials and Surface
Science Institute, University of Limerick Limerick V94 T19PX,
Ireland
– 7.7: Oxynitride Glasses.

Prescott, Patrick J.

Senior Engineer, Owens Corning Science & Technology Center,
Granville, OH 43023, USA
– 1.7: Simulation in Glass Processes.

Prinz, Sebastian

Business Development Director, Dorfner Analysenzentrum und
Anlagenplanungsgesellschaft mbH (ANZAPLAN), Scharhof 1,
92242 Hirschau, Germany
– 5.1: Chemical Analyses and Characterization of Glass.

Purnode, Bruno

Senior Research Associate
Owens Corning Science & Technology Center
Granville, OH 43023, USA
– 1.7: Simulation in Glass Processes.

Rapin, Christophe

Professor, Université de Lorraine
Institut Jean Lamour UMR 7198
Campus ARTEM, 2 Allée André Guinier, BP 50840
54011 Nancy Cedex, France
– 5.10: Glass/Metal Interactions.

Senior Expert Quality, Pharmaceutical Systems
Schott AG, Hattenbergstraße 10, 55122 Mainz, Germany
– 7.7: Glass for Pharmaceutical Use.

Preface

When art meets glassmaking: the visit of the Duchess of Berry (1798–1870) in 1824 to the plate-glass factory of the Royal Manufacture of Saint-Gobain as depicted by Édouard Pingret (1788–1869). The stifling heat, the noise of the furnaces, and the danger for the workers of the molten glass poured from the pot and spread with the steel roller on the large table (Chapter 10.9) have all vanished. Only the theatrical aspect of the scene remains, highlighted by the tall curtain, the duchess's light-colored dress echoing the worker's white smocks, and the children watching the show from the balcony. *Source:* Photo courtesy Saint-Gobain Archives.

The *Encyclopedia* has been designed to satisfy the needs and curiosity of a broad audience interested in the nature, properties, fabrication, and history of glass and looking for consistent, comprehensive, and up-to-date information in a single book. More than 100 chapters involving even more glass experts have been written in a perspective that combines the various aspects of this unique material, be they scientific, technological, industrial, historical, or cultural. Whether coming from academia or industry, the authors have in common a long practice of glass. Their goal is to be informative without being pedantic, to be concrete without being boring, and to give a balanced overview of the field – in a word, to allow a large readership to understand both the amazing properties of the vitreous state and its peculiarities compared with those of other states of matter. Excluding the so-called spin glasses and other kinds of disordered physical systems, the *Encyclopedia* restricts itself to what is now termed *structural* glass.

In all chapters, the authors discuss glass from a materials-science standpoint, but their purpose is not to review in any detail the latest advances of interest to specialists only. Rather, in the form of scholarly introductions, it is to present every topic at a uniform level and in a self-consistent manner. In this way, the main points will be grasped and key information of fundamental or practical use will be made available. The neophyte reader will then be able to consult the specialized literature and, in particular, the select bibliography appended to each chapter.

This approach does not imply that only elementary features are presented, but that concepts are appropriately introduced and any technical information clearly explained so as to avoid the common defect underlined in 1911 by the astronomer Percival Lowell (1855–1916) who emphasized in *Mars and its Canals* that “nothing in any branch of science is so little known as its articulation, — how the skeleton of it is put together, and what may be the mode of attachment of its muscles.” Whereas a very few chapters give a flavor of current technicalities involved in glass research, newly investigated topics are also considered with the goal of ensuring that the *Encyclopedia* remains a useful reference over an extended period of time. Although those views that are at this moment very speculative are generally not discussed at length, they may be stated in the final *Perspectives* of the chapters.

Given the diversity of topics treated, the name of *Encyclopedia* (*Kuklos paideia*, cycle of enlightenments, in Greek) is particularly appropriate. The surprising fact is that such a reference work was not existing at all for glass, in general, even though more than hundreds of thousands of encyclopedias have now been devoted to any topic worth of attention, including glass art in particular. The

Encyclopedia consists of 10 sections preceded by a general introduction and concluded by a postface. It begins with glassmaking and continues with structural, physical, and chemical properties. The stage is then set to turn to issues pertaining to light, to the main inorganic glass families, to organically related glasses, to environmental and other industrial issues, and, finally, to the main facets of the rich glass history. Even in more than 100 chapters, it has not been possible to deal with every important topic relevant to glass. A few more chapters would have been welcomed, but their advantages would not have outweighed the inconvenience of a longer publication time, especially for the *Encyclopedia* contributors.

Each section is preceded by a short introduction summarizing in a few sentences the contents of its chapters for helping readers to decide which ones fit their own interest best. Another purpose of these introductions is to show that, from the first to the last, the chapters are telling a consistent story. Although efforts have been made to avoid overlap, some limited duplication was inevitable to make sure that most contributions could be read independently of the others. Of course, boundaries between chapters or sections are not always clear-cut, so that some arbitrariness has been involved in their delineation. And whereas the scientific and technology contents of the chapters will probably speak for themselves, it might be useful to note that historical aspects are dealt with not only in the last section but also elsewhere each time they can help to open deeper perspectives. As for the *Culture* included in the title of the *Encyclopedia*, it is explicitly treated only in the very last chapter but pervades a great many others, for example, in the history section where beautiful pieces of art are in particular reproduced.

At the end of this endeavor, it is now a pleasure to acknowledge (i) the encouragement initially provided by R. Conradt, N.G. Greaves, J. Livage, J. Lucas, B. Mysen, A. Takada, and Y. Yue when the project took shape; (ii) the warm welcome this project received through G. Geiger and A. Lekhwani when submitted to the American Ceramic Society and John Wiley & Sons; (iii) the invaluable help then brought all the way by Reinhard Conradt and Akira Takada through their constant advice, support, friendship, and careful reviewing work; (iv) the great many graphics and pictures neatly prepared by Joël Dyon to highlight the matter presented in numerous chapters; (v) the efforts of 151 authors working in 23 countries who participated in this ambitious endeavor and went responsively throughout an editorial process aimed at ensuring an overall homogeneity of style and content, and incorporated in their texts the relevant historical and cultural aspects evoked by the *Encyclopedia* title; (vi) the thoughtful comments and apt observations provided

by nearly 200 reviewers whose names are included at the beginning of every chapter to recognize publicly their contributions; (vii) the original pictures or help in different matters generously provided by colleagues, friends, and institutions whose names are mentioned at the relevant places; (viii) the Humboldt Stiftung, the Ludwig-Maximilians-Universität, and Donald Dingwell for the fruitful work done in Munich; (ix) the so many things about glass or high-temperature techniques and processes discussed over the years with T. Atake, J.-L. Bernard, Y. Bottinga, R. Conradt, K.-U. Hess, R. Kerner, B. Mysen, G. Ottonello, J.-P. Petitot, J. Roux, A. Sipp, J.F. Stebbins, A. Takada, C. Téqui, and other colleagues too numerous to be mentioned; (x) the Table of ion data compiled by J.F. Stebbins, the help provided at various stages of this study by É. Fareau, B. Gasparyan, K.-U. Hess, A. Hofmeister, K. Meliksetian, B. Mysen, and M. Wolf as well as thoughtful comments by J.M. Parker and R.F. Tournier on the section introductions; (xi) and finally Michael Leventhal who oversaw the project at Wiley, Stefanie Volk for copy editing and Viniprammia Premkumar for smooth and responsive production of the book.

The *Encyclopedia* is dedicated to them and to all people whose efforts throughout the ages made glass the astonishing, ubiquitous material it has become.

1 A Historical Random Walk

1.1 The Glass Age

“Among the so many, so varied products, which attest to the industrial genius of mankind, there are very few that have uses as numerous as *glass*, whose properties are so wonderful,” pointed out in 1868 Georges Bontemps (1799–1883), a famous nineteenth-century glassmaker [1], who added: “no matter could replace glass in the most important of its uses.” At the same time, the great popularizer Louis Figuier (1818–1894) stated that it would be too long to list “the services that glass provides to science, the arts, industry, domestic needs, to the individual acts of man in society, to the poor and the rich, to the ignorant and to the learned.” Stressing that “household economics, science, civilization, progress and well-being, we owe almost all this to glass,” Figuier concluded that “born with primitive societies, glass will only disappear with civilization” [2].

Certainly, Bontemps and Figuier could not have guessed that organic polymers known as *plastics* would replace mineral glass in some of its traditional uses. Ironically, however, not only has mineral glass found many more, such as light guide in optical fibers (Chapter 6.4) or scaffold for bone regeneration (Chapter 8.4) to name only two of the latest, but most organic polymers are also glasses in the physical sense of the term. Since its very first origins, the vitreous state has thus opened astonishing ways to create original materials, to satisfy the most diverse needs and even to discover the world at large.

Unlike other well-established materials, glass has gone through more developments in the past 50 years than in two millennia from both industrial and technological standpoints. Whether overwhelming in the glazing of skyscrapers or hidden in telecommunication networks, glass has become still more ubiquitous in the modern environment than at Bontemps and Figuier’s time so that claiming that we are now living in the *Glass Age* is not an overstatement [3, 4]. Whereas original glass compositions have, for instance, been designed for innovative lighting, screen, and display applications (Chapters 6.9 and 6.10), even the traditional products used for glazing and containers are now taking advantage of various new functionalities (Chapters 6.7 and 6.8). But what might be the most fascinating modern feature of glass is the way in which the material can be engineered to satisfy the most opposite requirements. Long celebrated for light transmission (Chapter 6.1), glass can be made opaque to a wide range of electromagnetic radiations from infrared to X-ray wavelengths through addition of appropriately absorbing elements (Chapters 3.13 and 6.2). Chemical inertness is

another major traditional asset of glass, which is in contrast purposely avoided in *water glass* (Chapter 7.5) and bioactive glasses (Chapter 8.4) whose usefulness rests on their intrinsically high chemical reactivity. And whereas extremely low impurity levels are required in optical fibers and other optoelectronic devices (Chapters 6.3–6.6), storage of municipal and nuclear waste relies on the capacity of glass matrices to incorporate large amounts of a great many elements (Chapters 9.10 and 9.11).

Additional examples are not needed here to illustrate further the point as they will be found in numbers in the *Encyclopedia*. It is more appropriate to stress that most of these engineering developments have relied on the improved understanding of the glassy state brought by a better knowledge of its physical, chemical, and structural properties. What a long way has therefore been traveled since man made acquaintance with a strange, dark rock differing from all others by its luster and especially, when split into pieces, by its extremely sharp edges that even flint could not match!

1.2 An Economic Forerunner

Obsidian (Figure 1), a natural glass found in volcanic provinces in various parts of the Earth, has been known from time immemorial. From arrowheads (Figure 2) to blades of any kinds and purposes (Figure 3), its unique properties made it so valuable to hunter-gatherers that it was the very first item to be extensively exchanged over long distances [5]. Well before any man-made object was produced, obsidian thus embodied at an early stage of human evolution the economic notion of competitive advantage, which eventually resulted in its real trade (Chapter 10.1). At the heart of a dynamic corridor between Eurasia and Africa, present-day Armenia played a significant role in this history as a material source for a wide area in the Near East, initially through moving communities that were carrying their tools with them [6]. Armenia is also important because of the new light it has recently shed on the far-reaching issue of the expansion of archaic *Homo sapiens* out of Africa.

According to a claim often made, this expansion followed the important technical change from bifacial to Levallois technique of stone knapping (Figure 3, cf. [7] for their differences). At the Nor Geghi-I site, near Yerevan, both types of tools actually coexist within alluvial sediments sandwiched in between lava flows dated to

Figure 2 The delicate stone knapping of an arrowhead made possible by obsidian in Pre-Colombian present-day Arizona. Source: Photo courtesy Alexandra Navrotsky.

441 000 $\pm$ 6 000 and 197 000 $\pm$ 7 000 years [8]. From a fundamental standpoint, the synchronic use of both techniques by a single human group at this site thus indicates instead that, after human dispersion, the transition occurred independently within geographically distinct areas. From a practical standpoint, the change allowed better tools to be obtained so much faster from a large core (Figure 1) and with little waste. One could in fact conclude from the incredibly high abundance of artifacts buried in a Middle-Paleolithic site such as Barozh 12 [9], next to the Arteni Complex Volcano (Eastern Armenia), that the concept of disposable object was born with obsidian in the Paleolithic!

Man-made glass appeared considerably later, only three and a half millennia ago in the Late Bronze Age in a wide area ranging from the Near East to Egypt and Greece (Chapter 10.2). The vividly colored but expensive material newly produced was originally the preserve of elites who had recognized its aesthetic and practical interest. After 15 centuries of technical improvements and decreases of production costs, it became a basic commodity in the Roman Empire as acknowledged by Petronius (first century CE) in the *Satyricon* where one of his characters uttered: “You will forgive me if I say that personally I prefer glass; glass does not smell. If it were not so breakable I should prefer it to gold; as it is, it is so cheap” [10]. This chemical inertness achieved at reduced cost was of course one of the early assets of glass. As we now know, others were resulting from its lack of long-range atomic order, which makes forming in the most diverse shapes and sizes possible, produces optical isotropy, gives much flexibility in terms of raw materials and coloring elements thanks to the almost limitless extent of its solid solutions, and is at the source of mechanical properties in principle limited only by the strength of interatomic bonds thanks to the lack of weak grain boundaries.

How was it figured out that glass could completely lose its vivid colors, which first attracted man’s interest, we do not know. The transparency now so closely associated

Figure 3 The striking stone-knapping difference between a biface (left) and Levallois point and blade, all made from obsidian (right); length: 20 cm: (a) Acheulean hand axe produced by serial removal of small flakes with a soft hammer (Kuchak-3 open-air site, Aparan Depression, Central Armenia); (b) Levallois Mousterian point, with its plano-convex profile, produced before the reparation of core convexities, and the recurrent method, in which multiple Levallois flakes are detached before reparation (Barozh-12 open-air site, Ararat Depression, Eastern Armenia); (c) Regular flake of the Chalcolithic period produced by pressure flaking from a prismatic core with the aid of a lever (Mastara-1 settlement, Ararat Depression). Source: Photos courtesy Boris Gasparyan.

with glass was first achieved for very special pieces such as cups made in Achaemenid Persia in the fifth century BCE (Chapter 10.0, Figure 1a). But it took several more centuries before transparency became common. The existence of pure, natural carbonates commonly termed natron was the key ingredient to achieve it at a large scale at the beginning of our era [11]. Especially in the Levant, the competitive edge acquired by glassmakers thanks to this substance was such that it led to the establishment of a world market: finished items and glass ingots were traded along well-established commercial routes to be exported as far as East Africa and India [12], the ingots to be shaped locally in small workshops (Chapter 10.3). A first glimpse at globalization?

1.3 A Multifaceted Material

Glass has always aroused much curiosity by its virtue of embodying almost unlimited possibilities for transforming matter. Until the end of the nineteenth century, industrial illustrations of such transformations were the metamorphoses undergone by the large glass pieces that were first blown before being opened and flattened to yield flat panes with the neat fire finish required for transparency (Chapter 10.8). Nowadays, who has never been captivated by the work of a blower, by the action of a delicately controlled fire that gives birth to the most surprising shapes and, in a way, makes the material living for an instant? Even the proverbial brittleness of glass is part of this powerful imaginative world: its fracture indeed seems as unpredictable as it is dramatic, as illustrated by a tempered drinking glass suddenly exploding after several bounces when falling onto the ground.

To this kind of amazement also contributed early the miracles wrought by glass ever since it first restored sight to visually impaired people in the thirteenth century (Chapter 10.10). It is thus no wonder that Leonardo da Vinci (1452–1519) devoted efforts to design a device for machining eyeglasses. Shortly after, the transparent glazing of windows opened houses on the outside world at about the same time as the telescope and the microscope led to the discovery of the universe from the infinitely large to the infinitely small (Chapter 10.10). Grinding of optical lenses was then extensively practiced by Galileo Galilei (1564–1642) himself and considered a trade worth earning a living by the eminent philosopher Baruch Spinoza (1632–1677). That glassmaking had something special is actually indicated by the fact that, in France, it was long the only trade that the nobility could practice as *gentlemen glassmakers* without losing its special status.

To acknowledge all what civilization was owing to this material, the polymath and glassmaker Mikhail Vasilyevich Lomonosov (1711–1765) wrote in Russia a long poem entitled *Letter on the use of Glass*. “A whole year would hardly suffice me to reach the end of worthy praise for Glass” [13], Lomonosov thus claimed when mentioning not only the telescope, the microscope, or the barometer, but also the thrilling electrical researches of his time based on the accumulation of charges on the glass disks of electrostatic machines (Chapter 10.10). Such was the interest raised by the *vitreous* (positive) and *resinous* (negative) electricities “that people of all genders and ranks were then begging for the favor of being subjected to electric shock, to the point that the noble and courageous Professor Georg Matthias Bose (1710–1761) said with philosophical heroism: *I would not regret dying of an electric shock, since the account of my death would provide the subject of an article in the Memoirs of the Royal Academy of Sciences of Paris*” [14]. Could this admirable *philosophical heroism* have been elicited by a material other than glass?

At the same period, glass became the source of another kind of emotions when the famous Benjamin Franklin (1706–1790) was inspired by “the sweet tone that is drawn from a drinking glass, by passing a wet finger around the rim” [15] to design in 1761 the *glass armonica* whereby it was a set of overlapping wet glass cones of different sizes that was rotating to emit a *sweet, ethereal, or pathetic* tone through the friction of fingers. The instrument met with rapid success such that, beginning with Wolfgang Amadeus Mozart (1756–1791) [16], quite a few great composers wrote short pieces for it. The fashion for glass was such that a German living in Paris named Beyer presented in 1785 to the Académie des Sciences his *forte-piano* with glass plates, acted upon by wool-covered hammers, which Franklin christened *glass-cord* [17]. And it was a flute made from lead-crystal glass that the Parisian instrument maker Claude Laurent (d. 1848) patented in 1806 and produced in white, cobalt-blue, and uranium-green hues; in spite of its weight, its musical qualities and reduced temperature-induced pitch changes ensured its popularity for several decades [18].

This select series of anecdotes probably makes it unnecessary to emphasize again the importance of glass in daily and social life stressed above by Bontemps and Figuier. It might in contrast be useful to mention that the antique tradition or ornamental glass was revived at the same period by Georges Frédéric Strass (1701–1773), who became the French King’s jeweler, when he invented *strass*, or *rhinestone*, a high-lead crystal glass bearing various metal oxides that is still made today to imitate precious stones.

1.4 The Silica Paradoxes

1.4.1 Biogenic Silica vs. Flint

Historically, glass owes its importance to silicates. But what substances could have replaced silicate glasses in their diversity of uses on a silicon-free planet? The question would be moot if carbon – the next of kin of silicon in the Periodic Table – and, therefore, life and human beings would have also been lacking. More seriously, however, reflecting on the origin of the silica sources used in glassmaking is not a futile exercise.

It is not widely known that 15 billion tons of *biogenic* silica glass are yearly produced in seawater by diatoms, sponges, and some other living organisms. Such a biological production has major effects on the Earth's global ecosystem and has now become a *biomimetic* source of inspiration for designing wholly new materials (Chapter 8.1). Interestingly, biogenic silica also had noteworthy implications for glassmaking because of its recycling into the opal or microcrystalline quartz of *flint*. Flint, or *chert* as it is called in geology, is commonly found as abundant nodules horizontally embedded in limestone (Figure 4). Its deposition thus requires carbonate

dissolution followed by silica precipitation and, thus, percolating waters undersaturated with respect to calcium carbonates but oversaturated with respect to silica. Without going into the details of the process and of its control by pH and geological context [19, 20], it will suffice here to state that biogenic silica accumulating at the bottom of the sea is the source of the dissolved silica that reprecipitates as flint. And it happens that flint was the raw material used in England from the seventeenth century to remedy the lack of sand pure enough for making optical glass and luxury ware (Chapter 10.10).

In passing, one can also note that silica has been biogenically produced relatively late in evolution compared with calcite and aragonite, the main CaCO_3 polymorphs, but then met with immense success especially with diatoms. A major reason was the advantages of an amorphous compared with a crystalline substance in terms of optical or mechanical properties for the materials protecting the living organisms (Chapter 8.1); amorphous calcium carbonates do exist, but they serve instead as intermediate reaction steps, which are short lived and thus end up crystallizing [21], which is not surprising as molten CaCO_3 is

Figure 4 The abundant beds of black flint present in a 80-m high limestone cliff of the English Channel at the Pointe du Chicard in Yport (Normandy). Same beds of the Upper Cretaceous used in the past for making *flint* glass in England on the other side of the Channel. Height visible on the picture: 10 m. Source: Photo P. Richet.

Figure 5 The strong contrast between the potential energy changes induced by variations of Si-O distances and S-O-Si angles indicated by the calculated surfaces of constant energy of $\text{H}_6\text{Si}_2\text{O}_7$ clusters. Source: After [23].

not itself a good glass-forming liquid. Interestingly, formation of biogenic silica would have first been a way to evacuate toxic Si at too high concentrations from cells. By a twist of evolutionary history, it would have become a protecting device so efficient for organisms [22] that it has since then played a major role in the global ecosystem, causing, for instance, the Si concentrations to be so low in seawater.

1.4.2 A Quantum-Chemical Factory: The Production of Silica Sand

Although glassmaking would have been possible without sand, it is unlikely that flint would have led to the invention of glass as it requires thorough grinding to become a reactive raw material. Regardless of grinding costs, it is also doubtful that flint would have been a silica resource widespread and convenient enough for an expanding glass industry. The fundamental importance of silica sand thus remains undisputed. Geologically, sand is produced via the weathering of granite and related SiO_2 -rich igneous rocks. The most abundant rock of the Earth's crust, granite is made up of quartz and alkali $[(\text{Na},\text{K})\text{AlSi}_3\text{O}_8]$ and plagioclase $[(\text{Na}_x\text{Ca}_{1-x})\text{Al}_{2-x}\text{Si}_{2+x}\text{O}_8]$ feldspars. Whereas feldspars progressively transform into clay under the action of meteoric waters, quartz resists and accumulates as sand either on the spot or downstream.

The very presence of quartz at the Earth's surface appears to be a clear geochemical anomaly, however, which thus deserves some explanation. With typical 75 wt % SiO_2 , the melts from which granite crystallizes represent the end products of *magma differentiation* (Chapter 7.2). Owing to their very high viscosities, they rarely rise up to the Earth's surface to erupt as obsidian flows but crystallize slowly instead at some depth to yield large-grained rocks. These melts are the last produced after partial crystallization of primary magmas, which form themselves deep in the Earth's mantle by partial melting of SiO_2 -poor, MgO-rich rocks (~45 wt % for both oxides, along with ~7 % FeO, 2 % Al_2O_3 , 1 % CaO, and a few % at most alkali oxides). Because oxygen bonds more

strongly with silicon than with the other elements (Table A.1), one might think that SiO_2 -rich minerals should be the most refractory. As a result, the SiO_2 content of primary magmas should be lower than that of their source rock and decrease further through partial crystallization on their way up to the Earth's surface. Such a trend is opposite to the SiO_2 increase observed. It is in contrast consistent with the fact that cristobalite, the high-temperature polymorph of SiO_2 at room pressure, is less refractory than lime (CaO), periclase (MgO), and even forsterite (Mg_2SiO_4) whose melting temperatures are about 600, 800, and 175° higher than the 2000 K of cristobalite, respectively.

The paradox lies in the fact that bond strengths are usually considered within the framework of ionic forces, which are by definition nondirectional. Now, directionality is an inherent feature of Si-O bonding in view of its markedly covalent character. Because electron delocalization through polymerization and creation of Si-O-Si linkages is not large enough to constrain geometrically the arrangements of the SiO_4 tetrahedra, the same energy variations are, for instance, caused in $\text{H}_6\text{Si}_2\text{O}_7$ clusters by a small 0.02 Å change of the Si-O bond length and by a large 20° modification of the O-Si-O inter-tetrahedral angles (Figure 5). Bending of these linkages is thus so easy that configurational rearrangements take place without involving much energy [24]. The fact is most simply illustrated by the transitions of α -quartz and α -cristobalite to their dynamically disordered β -forms near 573 and 250 °C, respectively. Hence, fusion of these minerals does not require the breaking of bonds involved in ionic crystals. The SiO_2 enrichment and resulting quartz crystallization induced by magma differentiation are thus mainly driven by the sp^3 hybridization of silicon orbitals, which causes largely polymerized crystals to melt at temperatures much lower than would be expected from the Si-O and Al-O bond strengths [24]. In other words, the existence of silica sand originates in a quantum-chemical effect, without which glassmaking would not have existed.

2 Some Basic Concepts of Glass Science

2.1 From Metastability to Relaxation

The silica issue illustrates how answers to apparently simple problems can require in-depth analyses for which theoretical concepts presented in various chapters of the *Encyclopedia* should prove useful. To help readers whose knowledge of the glassy state is minimal, however, the rest of this introduction will be devoted to a brief presentation of some basic concepts pertaining to glass and nonequilibrium systems, which will thus not need to be commented upon in specific chapters.

In preamble, it would be useful to define precisely what a glass is before discussing any of its properties. In accordance with its intrinsically disordered nature, however, glass might be pleasantly defined as a material that is difficult to define in an unambiguous or fully consistent manner. In Chapter 10.11, a glass is nonetheless defined as a macroscopically homogeneous amorphous solid whose properties (physical, chemical, or structural) vary with its preparation conditions. Usual definitions differ depending on whether the emphasis is put on the disordered atomic structure of the material or on the existence of a *glass transition* separating a solid material at lower temperature from a supercooled liquid at higher temperatures. Because glass structures depend on the type of system considered, they are described in widely different ways for oxides, metals, or organic polymers so that they do not lend themselves to a brief, general presentation.

Although a glass transition cannot always be observed, its phenomenology and its implications on glass properties are in contrast common not only to all glass-forming liquids, but also to partially disordered systems such as *plastic crystals*. In view of their dual practical and theoretical importance, the main features of the glass transition will thus be summarized here in a qualitative way. Without making any reference to recent advances in the field, the purpose is simply to describe the phenomenology of vitrification and its effects on physical properties, to introduce some of the groundbreaking concepts that have been proposed to account for them, and to highlight some simplifying features thanks to which intrinsically complex glass problems become more tractable.

A main source of difficulty is that the *time* parameter must be considered because of the kinetic nature of the glass transition. In the backdrop is the way in which the Gibbs free energy of a glass-forming liquid would be minimized under given experimental conditions and, thus, the kinetics at which physical properties *relax* after changes in intensive thermodynamic variables (Chapter 3.7). The largest and most rapid decrease of the Gibbs free energy would of course be ensured by crystallization. To bypass it, it has been known from time immemorial that a melt must be cooled rapidly enough.

Other things being equal, vitrification is favored by large freezing-point depressions near eutectic compositions, which result in increased viscosities and reduced thermodynamic driving forces for crystallization.

With very few exceptions (e.g. [25]), however, supercooled liquids do crystallize more or less rapidly upon prolonged annealing. Perhaps also influenced by the early twentieth-century conception that glasses were supercooled liquids (Chapter 10.11), a commonly held assumption is that any glass would eventually crystallize. This assumption is in fact plainly contradicted by the 4.6-billion year old glasses found in meteorites (Chapter 7.1). What has ensured their long-term preservation has been the extremely dry conditions of extraterrestrial space, which have prevented them from weathering. Since their SiO₂-poor compositions would make them prime candidates for ready devitrification, the almost infinite metastability enjoyed by these glasses is especially significant. The crystallization issue will thus be left aside in the following.

2.2 Relaxation: Phenomenological Aspects

Atomic mobility is the hallmark of the molten state as illustrated by the ready flow of a liquid adjusting to the shape of its container. Contrary to crystals where atomic positions are fixed and strongly constrained by long-range symmetry, liquids are characterized by dynamic disorder, i.e. by unceasing atomic rearrangements. This structural incompatibility between a crystal and a liquid makes any progressive transformation of one phase into the other impossible. In contrast, the vitrification of liquids is clearly a continuous process during which disordered structures become frozen in as revealed by progressively increasing viscosities, which eventually becomes so high that the materials have mechanically become a solid.

At high temperatures, the liquid is in internal thermodynamic equilibrium because its properties are time independent and uniquely determined by two intensive variables, usually taken to be pressure and temperature. At high viscosities, however, this simplicity no longer holds true as seen if one exerts a stress on the liquid at constant temperature or change the temperature at constant stress (Figure 6a). For a window glass [26], a constant, equilibrium shear viscosity is, for example, reached more rapidly in the former case than in the latter but this difference does not need to be commented upon here because pressure and temperature changes are of a different nature. Of greater importance is that Boltzmann superposition principle (Chapter 10.11) applies because, if both perturbations are simultaneously exerted, the response of the system is the sum of the two individual responses (Figure 6a).

In practice, temperature changes matter most. When high viscosities are measured at successively lower temperatures and then at higher temperatures (Figure 6b), two conclusions follow: (i) the time needed to reach the

Figure 6 Viscosity relaxation of window glass (Source: Data from [26]). (a) Time dependence of the viscosity at 788 K after: (1) application of a 110 MPa stress; (2) a temperature change from 819 to 788 K with this stress; (3) exerting simultaneously these stress and temperature changes. (b) Attainment of the equilibrium viscosity; sample equilibrated at 795 K, then quickly brought for equilibration at 788 K and at 777 K (open symbols) before following the same procedure for reversing the equilibrium values first measured at 788 and 795 K (open symbols).

constant equilibrium values increases tremendously with decreasing temperatures; (ii) the approach to equilibrium is slower when the sample was previously equilibrated at a lower than at a higher temperature. Hence, the rate at which these changes occur depends not only on temperature but also on the thermal history of the sample, i.e. on the instantaneous structure as well. Because thermodynamic equilibrium is reached when the structure has adjusted to the new intensive parameters, the process is termed *structural relaxation*.

To characterize the rate at which the shear viscosity (η) or any other property Y approaches a new equilibrium value, Y_e , one defines the relaxation time, τ_Y , as

Figure 7 Viscosity of window glass; solid line VFT fit to the data; dashed line: Arrhenius fit made to the high-temperature measurements; arrow: onset of departure from the equilibrium viscosity; solid squares and line: isostructural viscosities. Source: Data from [26, 27].

$$\tau_Y = -(Y_t - Y_e) / (\partial Y / \partial t), \quad (1)$$

where Y_t is the value actually measured at time t . If τ_Y were constant, the relaxation would be exponential:

$$(Y_t - Y_e) = (Y_0 - Y_e) \exp(-t/\tau_Y), \quad (2)$$

where Y_0 is the initial Y value, so that after a time τ_Y , the variation of Y would be a fraction $1/e$ of the initial departure from the equilibrium value. Regardless of the actual non-exponential nature of relaxation, measurements, for example, made on window glass at 777 K point to relaxation times much higher than one hour (Figure 6b). A measurement performed in only a few minutes would thus refer to a fixed configuration, i.e. to a glass. Depending on the timescale of the experiment, one observes that the nature of response is thus either liquid- or solid-like.

The glass *transition range* is that temperature interval where, depending on the timescale of the experiment performed, time-dependent observations are made. It signals the change from the liquid state, where a great many different atomic configurations are unceasingly explored, to another state where atoms become trapped in fixed positions and properties become again time independent. In statistical-mechanical jargon, this change is said to represent the loss of *ergodicity* and, thus, of internal thermodynamic equilibrium.

Experimentally, the loss of equilibrium can be readily followed by viscometry. Over an interval as wide as 10 – $10^{15.5}$ Pa·s, the viscosity of a glass-forming melt can be reproduced empirically with the Vogel–Fulcher–Tammann (VFT) equation (Chapters 4.1 and 10.11):

$$\log \eta = A + B/(T - T_1), \quad (3)$$

where A , B , and T_1 are constants (Figure 7). If only high-temperature measurements are considered, then a simpler Arrhenius equation is generally adequate, viz.

$$\log \eta = \log \eta_0 + \Delta H_\eta / RT, \quad (4)$$

where η_0 is a pre-exponential term and ΔH_η the activation enthalpy for viscous flow. Consistent with the aforementioned effects of thermal history (Figure 6b), the increasing departure of the viscosities from an Arrhenius fit made to the high-temperature data (Figure 7) indicates that, independently of any thermal-energy decrease, the structural rearrangements induced by lower temperatures progressively hinders viscous flow. The effect is still more apparent when measurements are made rapidly such that structural relaxation does not take place. Under these conditions, the *isoconfigurational* viscosity is indeed lower than the viscosity of the equilibrium supercooled liquid at the same temperature (Figure 7).

2.3 The Glass Transition

2.3.1 Standard Glass-Transition Temperature

For the experimental timescales of the order of a few minutes typical of measurements of macroscopic properties, one observes that, regardless of chemical composition, time-dependent results begin to be observed when the viscosity becomes higher than about 10^{12} Pa. For convenience and comparison purposes, one defines the *standard* glass-transition temperature, T_g , as the temperature at which the viscosity of the liquid reaches this value of 10^{12} Pa.s.

2.3.2 Volume Effects

The enhanced thermal expansion coefficient observed upon heating of a glass rod in dilatometry experiments is one of the most familiar manifestations of the glass transition (Figure 8a). The marked increase over an interval of about 50 K is rapidly followed by sample collapse because the viscosity rapidly decreases so much that the sample begins to flow under its own weight before structural relaxation is complete. As a result, the volume thermal expansion coefficient [$\alpha = 1/V (\partial V / \partial T)_P = 3/l (\partial l / \partial T)_P$] may be rigorously determined from the slope of the dilatometry curve for the glass, but not for the supercooled liquid.

In dilatometry experiments, one usually defines the glass-transition temperature as the intersection of the tangents to the lower- and higher-temperature curves. This temperature generally differs somewhat from the standard T_g simply because the glass transition depends on the particular experimental conditions of the experiment. With respect to enthalpimetry, dilatometry has the advantage of yielding absolute values of the property of interest, namely, the volume (and density). The influence of thermal history on density can thus be readily determined (which is why it was observed as early as in 1845, cf. Chapter 10.11). In contrast, the thermal expansion coefficient of glasses generally does not markedly

Figure 8 Volume effects of the glass transition. (a) Linear thermal expansion coefficient of E glass (Chapter 1.6) heated at 10 K/min; l = sample length (Source: Data from [28]). (b). Dependence of the volume of a glass on its fictive temperature.

depend on thermal history. At least above room temperature. The volumes of glasses produced at different cooling rates will then plot as a series of parallel lines (Figure 8b). To characterize the state of the glass, it suffices to know the temperature at which equilibrium was lost, which is directly given by the intersection of the glass and supercooled volumes (Figure 8b). This parameter is called the *fictive temperature* ($\bar{T}$), which thus represents the temperature at which the configuration of the glass would be that of the equilibrium liquid (Chapter 10.11). Knowing $\bar{T}$, it is then straightforward to determine the glass volume as a function of the fictive temperature, for example, at room temperature (Figure 8b).

2.3.3 Frequency Dependence

For exploring further the kinetics of the glass transition, one can vary the experimental timescale not only through

changes of the heating rate for a given technique, but through changes of the technique itself. In view of their relative simplicity, acoustic measurements of the adiabatic compressibility are especially interesting in this respect. For an isotropic solid, this compressibility is related to the velocities of compressional (v_p) and transverse (v_s) acoustic waves by:

$$\beta_S = 1/[\rho(v_p^2 - 4/3v_s^2)], \quad (5)$$

where ρ is the density. In a liquid of low viscosity, the attenuation of compressional waves is so rapid that one can usually consider that these waves do not propagate at all, in which case the compressibility reduces to

$$\beta_S = 1/\rho v_p^2. \quad (6)$$

Acoustic measurements are typically made with transducers working at MHz frequencies. Under these conditions, the response of the material to the compression exerted adiabatically by the acoustic waves is probed at timescales of the order of 10^{-6} seconds. To be induced by an acoustic wave, configurational changes must thus take place at timescales at least 10^6 – 10^7 shorter than those of dilatometry or calorimetry experiments. Their onset is thus correlatively observed at much higher temperatures. For a sodium silicate (Figure 9a), they are revealed above 700°C by a temperature interval where

v_p decreases markedly and becomes frequency-dependent. With respect to dilatometry or calorimetry experiments, the glass transition shifts from about 500 to 900°C , with a difference of about 50° between the measurements made at 1 and 5.6 MHz. At higher temperatures, equilibrium values of the compressibility are finally measured near 1100°C when the ultrasonic velocity becomes independent of frequency.

Experiments can be made at even shorter timescales when hypersonic sound velocities are measured by Brillouin inelastic scattering of photons by phonons (Chapter 2.2). At the timescales of the order of 10^{-10} seconds of these interactions, the glass transition shifts to higher still temperatures. For calcium aluminosilicates (Figure 9b), relaxed compressional velocities are typically observed only above 2200°C [30] where they begin to match the values determined by ultrasonic methods (Figure 9b). The first effect noticed when the temperature is increased is a slight kink (at around 750°C in Figure 9b), which disappears if the velocities are plotted against the volume of the sample instead of its temperature. This kink thus signals the increase in thermal expansion at the volume glass transition, whereas structural relaxation at the extremely short timescale of Brillouin scattering experiments becomes significant only at much higher temperatures. Interestingly, the shear sound velocities can then be measured for the supercooled liquid

Figure 9 Frequency dependence of the glass transition range. (a) Compressional acoustic-wave velocities of sodium disilicate measured at the frequencies (MHz) indicated (Source: Data from [29]); larger width of the glass transition range than in dilatometry because of the actual distribution of relaxation times. (b) Compressional hypersonic sound velocities measured for $36 \text{ SiO}_2 \cdot 16 \text{ Al}_2\text{O}_3 \cdot 48 \text{ CaO}$ melt (mol %) by Brillouin scattering and ultrasonic methods. Figure 10 Time dependence of the boundary between the glass and liquid phases of $\text{CaAl}_2\text{Si}_2\text{O}_8$. Source: Data from [32].

well above the standard glass-transition temperature as long as its viscosity is not too low [32]. The material is not really a “glass” because its configuration changes rapidly with temperature, but a “glass-like” material whose solid-like part of its acoustic properties may be probed. Finally, another noteworthy feature of the glass transition range is its markedly increasing width apparent from Figures 8b to 9a and b, which originates in the fact that a distribution of relaxation times, and not a single time, must be considered. Complete relaxation is thus controlled by the slowest mechanisms whose retarding effects are the greatest for the shortest experimental timescales.

In conclusion, the question as to whether a given substance is a liquid or a glass cannot be answered if the observational timescale is not specified. One must consider instead that the transition between the two kinds of phases is represented by a curve in the timescale–temperature plane (Figure 10). The picture is actually still more complex because the glass transition also depends on pressure. With the exception of some open 3-D network structures, T_g generally increases with pressure because an increasing compaction makes configurational rearrangements more difficult. At constant timescale, the glass transition is thus represented by another curve in the pressure–temperature plane (Figure 11). And the description is still more complex if the effects of composition are also considered. If all factors are dealt with together, the glass transition then becomes a

Figure 11 Pressure dependence of the glass transition of atactic polystyrene. Source: Zero-frequency Brillouin scattering data from [33].

hypersurface in the pressure–temperature–composition–timescale space.

2.3.4 An Irreversible Transition

The glass transition was first signaled by anomalous increases of the heat capacity, and its kinetic nature by the dependence of these anomalies on the thermal histories of the samples investigated (Chapter 10.11). Such effects are clearly apparent in early C_p measurements made on B_2O_3 (Figure 12a) where three different temperature intervals are distinguished [34]. Above about 270 °C, the liquid phase is in internal thermodynamic equilibrium because its heat capacity is uniquely defined by temperature (and pressure). In the 270–100 °C interval, internal equilibrium is lost as C_p is no longer defined by temperature only. The measurements made upon heating and cooling differ and C_p differences of up to 20% are found between samples initially cooled rapidly and slowly. Also noteworthy is the fact that the observed C_p hysteresis prevents a reversible thermodynamic pathway from being followed. It points instead to the creation of entropy through cycling in this interval and, therefore, demonstrates the irreversibility of the glass–liquid transformation.

Below 100 °C, C_p depends again only on temperature. If integrated from 270 to 100 °C, however, the C_p and C_p/T differences between the rapidly and slowly cooled samples represent enthalpy and entropy differences, respectively. These are constant below 100 °C as the glass C_p does not depend sensitively on thermal history. They can be readily calculated for any two glasses, like a volume difference, if their fictive temperatures are known (Chapter 3.6). An important conclusion then follows: the existence of an entropy difference at 0 K between

Figure 12 Irreversibility of the glass transition: heat capacity hysteresis measured for boron oxide upon cooling and upon heating of a slowly (S) and rapidly (R) cooled glass [34]. (b) Enthalpy and C_p differences between glasses cooled at different rates q ; Sup. liq.: enthalpy of the equilibrium supercooled liquid.

two samples implies that glasses have a residual entropy at 0 K: hence, glasses do not obey the third Law of thermodynamics because of the irreversible nature of the glass transition (cf. Chapters 3.6 and 10.11).

In more detail, the C_p hysteresis results from the observed contrast between a smooth decrease upon cooling and sharp increases upon heating followed by overshoots right at the end of the transition (Figure 12a). The former decrease simply points to the progressive loss of atomic mobility with decreasing temperatures. Upon

heating, the situation is more complicated because relaxation resumes at the temperature at which it vanished on cooling, but its first effect is to lower the enthalpy of the glass to bring it closer to the equilibrium values of the supercooled liquid (Figure 12b). At higher temperatures, the enthalpy curve of the material has already crossed that of the supercooled liquid when relaxation becomes almost complete at the timescale of the experiment. The heat capacity then increases rapidly (Figure 12b) in a way that depends on thermal history. The rise is highest for samples initially cooled down at the slowest rates, whose enthalpy is initially the lowest, or for samples heated at the highest rates. If the heating and cooling rates are increased, the transition shifts to higher temperatures because the decrease of the experimental timescale must be matched by an analogous decrease of the relaxation time (Figure 12b).

Determination of a glass-transition temperature is more complicated in calorimetry than in dilatometry because of the complex shapes of the observed C_p variations or even of the endothermic peaks recorded in thermal analysis. This temperature may, for instance, be taken as the inflection point of the C_p increase upon heating, but it can alternatively be defined in different ways so that is generally needed to specify which particular one has been selected [35].

2.3.5 The Case of Plastic Crystals

This description of the glass transition applies to a variety of kinetically controlled processes in crystals. *Plastic crystals*, characterized by low entropy of fusion and an unusually high plasticity, are good examples of disordered systems with three-dimensional long-range order. When the high-temperature form of cyclohexanol (ChI), for instance, crystallizes at 299 K, the $C_6H_{12}O$ molecules order in a face-centered cubic lattice but their regular shape allows them to maintain orientational mobility by rotations around the lattice points. It is through a transition to the low-temperature polymorph (ChII), which is stable below 265 K, that this dynamics vanishes and the orientational disorder disappears [36]. With rapid cooling rates, the ChI form can be obtained metastably and kept for long periods of time below 180 K. On further cooling, a transition is eventually observed near 160 K (Figure 13). The orientational disorder of $C_6H_{12}O$ molecules is then frozen in within the crystal. In contrast to the ChII form, whose entropy is zero at 0 K, ChI has a residual entropy of 4.7 J/mol K. The similarity with the glass transition phenomenology is such that the name of *glassy crystals* has been proposed for crystals where rotation of molecular groups is freed above a glass-like transition temperature and gives rise to relaxation

Figure 13 The calorimetric signature of orientational disorder in cyclohexanol plastic crystal. Measurements made upon heating with a gap from slightly above the glass-transition temperature T_g and the melting temperature T_f because of rapid transformation into the stable, ordered polymorph. Source: Data from [36].

phenomena much more complex than summarized here (Chapter 8.6).

2.3.6 Maxwell Model

In view of the continuous pathway between the liquid and glass states, glass-forming liquids cannot be purely Newtonian when they approach the glass transition. In fact, they are *viscoelastic*, with an elastic component that becomes increasingly important near T_g . More precisely, application of a shear stress first causes an elastic strain, which would be recovered if the stress were released, and then a viscous deformation. The response of a viscous melt subjected to stress thus is made up of an instantaneous, elastic response along with a delayed response. By combining the simplest representations of elasticity and viscous flow, Maxwell model has as a mechanical analogue a spring and a dash pot placed in series [37]. Its important result is that, if stresses are applied at low frequencies, as usually the case in viscometry, then a simple relationship holds between the viscosity, relaxation time, and shear modulus at infinite frequency (G_∞),

$$\eta = G_\infty \tau. \quad (7)$$

The fact that the glass transition is observed at values close to 10^{12} Pa.s for widely different kinds of liquids thus indicate that G_∞ also weakly depends on composition, with a mean value of about 10 GPa, which varies by less than a factor of 10 with either temperature or composition at least for oxide glass-forming liquids [38, 39]. Compared with the tremendous variations of viscosity with temperature and composition, G_∞ thus is almost constant. If the viscosity is known, structural relaxation times can be readily estimated from Eq. (7).

2.4 Configurational Properties

2.4.1 Equivalence of Relaxation Kinetics

It is usually more difficult to account for the kinetics of a reaction than for its thermodynamics. Relaxation in glass-forming systems does not depart from this rule. Whereas a single-order parameter such as the fictive temperature may be appropriate for characterizing the volume or enthalpy of a glass, relaxation kinetics requires models much too complex to be discussed here (see Chapter 3.7). One can nonetheless have a first look at the mechanisms involved in relaxation by examining whether their kinetics varies or not with the particular property considered.

As done for viscosity, the kinetics of volume equilibration can, for instance, be measured by isothermal dilatometry experiments. If samples with the same thermal history are studied, comparisons between the relaxation kinetics of different properties can be made in terms of normalized variables

$$Y = (Y_t - Y_\infty)/(Y_0 - Y_\infty), \quad (8)$$

where Y_t , Y_∞ , and Y_0 are the property Y at time t , initial time, and equilibrium, respectively. To within experimental errors, experiments on E glass, for example, show in this way the same kinetics for viscosity and volume (Figure 14).

More general conclusions are readily derived from comparison between different glass-transition temperatures even though these are not necessarily defined in the same way in different kinds of measurements. What is important is that they be defined consistently and refer to samples with the same thermal histories. For volume

Figure 14 Kinetics of equilibration for the viscosity and volume of E glass. Differences between the ascending branches mainly due to the uncertainties on the Y_0 values caused by unrecorded relaxation during the initial thermal equilibration of the sample. Source: Data from [28].

and enthalpy, the latter condition is fulfilled in dilatometry experiments and differential thermal analyses performed simultaneously, whose results can also be compared with standard glass-transition temperatures (Figure 15). The close 1 : 1 correspondences found in this way for the three temperatures of silicates, calcium aluminosilicates, titanosilicates, and borosilicates over a 400 K

interval thus confirm the equivalence of the relaxation kinetics for differing properties [28]. In other words, one must conclude that the same configurational changes are involved in enthalpy, volume, or viscosity relaxation at least in oxide systems, which illustrates their overall cooperative nature.

2.4.2 Vibrational vs. Configurational Relaxation

The equivalence of relaxation kinetics allows an important distinction to be made between vibrational and configurational contributions to the properties of glass-forming liquids. In preamble, one should note that relaxation in solids does not need to be specifically addressed, as long as macroscopic properties are concerned, because it takes place at the 10^{-14} – 10^{-12} seconds timescale of atomic vibrations. This instantaneous vibrational response persists in liquids where it combines with the configurational response whose timescale markedly decreases with increasing temperatures (Figure 16). For volume, isothermal dilatometry experiments near the glass transition may yield these two contributions (Figure 17) whose relative magnitudes directly reflect the increase in thermal expansion at the glass transition [40]. For the compressibility, another approach may take advantage of experiments made at different timescales. As described above, in certain temperature ranges, ultrasonic measurements yield the equilibrium adiabatic compressibility whereas Brillouin scattering experiments probe only its vibrational part. The configurational compressibility is then given by the difference between these two results [32]. That such determinations are actually scarce is not too problematic for second-order thermodynamic properties because, at least as a first approximation, one can assume that the vibrational contribution is represented by the glass property and the configurational one by the variations of these

Figure 15 Equivalence of the relaxation kinetics for the enthalpy, volume, and viscosity illustrated by 1 : 1 correlations between the relevant glass-transition temperatures determined by differential thermal analysis (DTA), dilatometry (dil), and viscometry (vis, i.e. standard T_g). Figure 17 Vibrational and configurational contributions to the volume change of $\text{CaMgSi}_2\text{O}_6$ liquid after an abrupt temperature decrease from 982 to 972 K. Source: Data from [40], cf. Chapter 3.5.

properties at the glass transition. In silicate systems, the configurational heat capacity can thus be written

$$C_{\text{pl}}^{\text{conf}}(T) = C_{\text{pl}} - C_{\text{pg}}(T_{\text{g}}), \quad (9)$$

where the subscripts l and g refer to the liquid and glass phases, respectively, and a further simplification arises from the fact that $C_{\text{pg}}(T_{\text{g}})$ may be considered to be the Dulong–Petit harmonic limit of $3R/\text{g atom}$ (R = gas constant) the isochoric heat capacity [41].

2.4.3 A Microscopic Picture

The vibrational/configurational split can be simply illustrated by a schematic one-dimensional representation of interatomic potentials (Figure 18). Contrary to crystals, where these potentials have a long-range symmetry, glasses have essentially a short-range order because the bond angles and distances between next-nearest neighbor atoms are not constant but spread over a range of values. The minima of potential energy, which determine the glass configuration, are separated by barriers with varying heights and shapes [43]. When thermal energy is delivered to the glass, the subsequent temperature rise is associated only with increasing amplitudes of vibration of atoms within their potential energy wells. Like for any solid, the heat capacity of the glass is, therefore, only vibrational in nature.

Figure 18 One-dimensional schematic representation of interatomic potentials. Inset: potential-energy landscape for a strong and a fragile liquid (Source: After [42]). C: crystal; IG: ideal glass; MC: metastable crystal.

At sufficiently high temperature, thermal energy increases to the point that atoms can overcome the barriers that separate their own from the neighboring potential energy wells (Figure 18). This onset of atomic mobility signals structural relaxation. If the relaxation time is longer than the experimental timescale, however, only the vibrational heat capacity is measured. If the temperature is increased further, or if time is sufficient for the new equilibrium configuration to be attained during the measurement, then the configurational heat capacity is also measured. When integrated over all atoms, the configurational heat capacity represents the energy differences between the minima of the potential energy wells that are explored as temperature increases (Figure 18).

The glass transition can thus be viewed as the point from which atoms begin to explore positions characterized by higher potential energies. Regardless of the complexity of this process at a microscopic level, this spreading of configurations over states of higher and higher potential energy is the main feature of atomic mobility. As a consequence, configurational heat capacities are positive. This feature, in turn, is consistent with the fact that any configurational change must cause an entropy rise when the temperature increases as required by Le Chatelier principle. As for relaxation times, they decrease with rising temperatures because large thermal energies allow potential energy barriers to be overcome more easily.

Another general feature of interatomic potentials is their anharmonic nature: displacements of the vibrating atoms from their equilibrium positions are not strictly proportional to the forces exerted on them. Because increasing vibrational amplitudes result in increasing interatomic distances (Figure 18), the thermal expansion

coefficient is generally positive for glasses. In the liquid, it increases markedly when even greater interatomic distances result from configurational changes.

2.4.4 Compressibility and Permanent Compaction

An important difference between crystals and liquids concerns the effects of pressure on their structures. The former are stable as long as the variations in their bond angles and distances induced remain consistent with their long-range symmetry. A transition to a new phase takes place when this constraint is no longer respected. In contrast, the lack of long-range order makes a wide diversity of densification mechanisms possible in a liquid, whose structure thus keeps constantly adjusting to varying pressures through changes in short-range order characterized by shorter equilibrium distances and steeper slopes around the minima pictured in Figure 18. The compressibility is thus greater for a liquid than for its isochemical crystal. It is also made up of vibrational and configurational contributions. Because the shape of interatomic potentials determines the vibrational energy levels, compression is termed vibrational for the elastic part of the deformation. As for the configurational contribution, it is related to the aforementioned changes in the potential energy wells.

If a liquid is quenched as a glass at high pressure, the final glass recovered after decompression will be denser than its counterpart formed at room pressure because only the vibrational part of the compression is eventually recovered (Figure 19). But permanent densification can also be achieved at room temperature through compression of a glass at a few tens of kbar (Chapter 10.11). The effects of pressure and temperature on the properties of glasses are thus of a different nature since the kinetics

Figure 19 Permanent compaction of polyvinyl acetate after compression at 800 bar (80 MPa) in the liquid state. Source: Data from [44].

of pressure- and temperature-induced configurational modifications are markedly different for given frequencies or experimental timescales. This dissimilarity mainly originates in the fact that the shape of potential energy wells varies little with temperature, but significantly with pressure. If a high kinetic energy is needed to overcome potential barriers at constant pressure, the changes in these barriers with pressure can lead by themselves to new configurational states, at low temperatures, if the pressure is high enough.

2.4.5 Kauzmann Paradox

When viscous liquids escape crystallization, why do they eventually vitrify instead of remaining in the supercooled liquid state? One answer to this question is purely kinetic and relies only on increasingly long relaxation times on cooling. If experiments could last forever, any glass would eventually relax to the equilibrium state. Then, the glass transition would result only from the limited timescale of feasible measurements. A simple thermodynamic argument known as Kauzmann's paradox [45] indicates that this answer is incorrect. At its basis is the existence of a configurational contribution that causes the heat capacity of a supercooled liquid to be generally higher than that of an isochemical crystal and its entropy to decrease faster than that of a crystal when the temperature is lowered (Figure 20). If the entropy is extrapolated to temperatures

Figure 20 Kauzmann catastrophe for amorphous selenium and ortho-terphenyl (C_8H_{14}). Differences between the glass transition and Kauzmann temperatures indicating the smallness of the C_p extrapolations performed. Source: Data from [46, 47].

below the glass transition range, it becomes lower than that of the crystal at a temperature T_K , which is high enough for such an extrapolation to remain reasonable. Although this situation is not thermodynamically forbidden, it seems unlikely that an amorphous phase could have a lower entropy than an isochemical crystal.

The conclusion is that an amorphous phase cannot exist below T_K . The temperature of such an entropy catastrophe constitutes the lower bound to the metastability limit of the supercooled liquid. As internal equilibrium cannot be reached below T_K , the liquid must undergo a phase transition before reaching it. This is, of course, the glass transition. In its original form, Kauzmann's paradox implicitly neglects possible differences in vibrational entropy between the amorphous and crystalline phases. This simplification is actually incorrect but it does not detract from the gist of the argument, for taking into account such differences would only shift T_K slightly. A more rigorous statement of the paradox is that the catastrophe would occur when the configurational entropy of the supercooled liquid vanishes.

2.4.6 Potential Energy Landscape: Ideal Glass and Fragility

Among the great many statistical mechanical models that have attempted to account for the glass transition and solve Kauzmann's paradox, the early one proposed by Gibbs and Di Marzio [48] is of special interest. It predicts that the supercooled liquid would transform to an *ideal* glass through a second-order transition at the temperature T_0 at which its configurational entropy would vanish. Since then, the existence and the nature of such a transformation have been much debated. This debate notwithstanding, the important point for our discussion is the result subsequently derived by Adam and Gibbs [49] on the basis of a lattice model of polymers. This result is a very simple relationship between relaxation times and the configurational entropy of the melt, viz.

$$\tau = A_e \exp(B_e/TS^{\text{conf}}), \quad (10)$$

where A_e is a pre-exponential term and B_e is approximately a constant proportional to the Gibbs free energy barriers hindering the cooperative rearrangements of the structure.

Qualitatively, this theory assumes that structural rearrangements would be impossible in a liquid with zero configurational entropy so that relaxation time would be infinite. If two configurations only were available for an entire liquid volume, mass transfer would require a simultaneous displacement of all structural entities. The probability for such a cooperative event would be extremely small, but not zero, and the relaxation times would be extremely high, but no longer infinite. When

configurational entropy increases, the cooperative rearrangements of the structure required for mass transfer can take place independently in smaller and smaller regions of the liquid.

Within this picture, relaxation is determined by the topology of potential energy wells in an n -dimensional space and, particularly, by the density and relative depths of these wells as may be illustrated in a 1-d representation of such a *potential-energy landscape* (Figure 18, insets).

Figure 21 Fragility as a measure of the extent of temperature-induced configurational changes in inorganic and organic glass-forming liquids: correlations between relative C_p increases at the glass transition and deviations of viscosities from Arrhenius laws (Source: After [52]). Lower panel, from top to bottom: SiO_2 , GeO_2 , BeF_3 , ZnCl_3 , LiCH_3COO , $4 \text{ Ca}[(\text{NO}_3)_2] \cdot 4 \text{ H}_2\text{O}$, *o*-terphenyl, glycerol ($\text{C}_3\text{H}_8\text{O}_3$), and $\text{H}_2\text{SO}_4 \cdot 3 \text{ H}_2\text{O}$.

A simple distinction can then be made between strong and fragile liquids [43, 50]. For the former, a low density of wells translates into a small configurational heat capacity and entropy and thus, in small departures from an Arrhenian temperature-dependence of relaxation times as given by Eq. (7); for the former, the high density of wells is in contrast associated with high configurational heat capacities and entropies, and marked deviations from Arrhenian temperature dependences.

Owing to the simple proportionality between relaxation times and viscosity, this difference may be simply visualized in plots of viscosities as a function of T_g/T where T_g is the standard glass-transition temperature [51]. A well-known sketch (Figure 21) illustrates the point for a variety of inorganic and organic glass-forming liquids [52]. As particularly exemplified in Chapter 4.1, this duality between fragile and strong liquids will be a recurrent theme in many other chapters of the *Encyclopaedia* to which the reader is thus referred.

Numbers in brackets denote the uncertainties in the final decimal places. Reported values by definition exact when no uncertainties are mentioned.

Section I. Glassmaking

Figure 1 The initial melting step in the making of float glass: the 1-m deep bath of raw materials melted by the flames of a cross-fired furnace (Chapter 9.7). Pulls ranging from 500 to 1000 tons/day and mean residence times of at least 24 hours. Electro-fused refractory materials made up of alumina-zirconia-silica in contact with the melt, and of alumina and alumina-silica elsewhere (cf. Chapter 9.8). *Source:* Photo courtesy Simonpietro Di Pierro, Saint-Gobain Research Paris.

Compared with crude steel (1700 million tons/year worldwide) and especially with cement (4300 Mtons), glass (about 120 Mtons) is produced in relatively small quantities. In terms of product value or volume, however, the imbalance is significantly reduced since the cost of cement is about one sixth of that of window glass and steel about three times as dense. But what differentiates glass most from these other two inorganic pillars of modern civilization is the remarkable diversity of its uses illustrated throughout the Encyclopedia.

In Europe, for which the data are the most readily available, the 35 Mtons produced in 2017 were split into container (21.4), flat (10.1), domestic (1.3), reinforcement (0.7), and other (1.1) glass. For both container and flat glass, the world market is estimated to be in the 60–80 billion \$ range and is expected to keep growing in the years to come at yearly rates higher than 5% on average, with large geographical differences (cf. Chapter 9.6). And growth rates should be higher still for new products such as the *smart* glass used in a variety of electronic devices (cf. Chapter 6.10), whose market should increase by a factor of 3 from 2017 to 2023 from the current few billion \$ per year.

Like cement and steel producers, glassmakers sell more than 90% of their production to other industries. Most uses of glass are nonetheless familiar to anyone. These are summarized in the first chapter of this section where R. Conradt points out their strong dependence on chemical composition of the glasses and on their ensuing physical properties, explaining that the reason why the still-dominant soda-lime silicates were empirically found so early in the history of glassmaking is simply because they lie close to the eutectic of the $\text{Na}_2\text{O}-\text{CaO}-\text{SiO}_2$ system.

Even though glass is now made in many different ways for different applications, the traditional procedure of making it by cooling of a batch melted at high temperatures remains by far prevailing. As one readily realizes when looking at the original glazing of late-nineteenth-century buildings, the long-standing problem faced by glassmakers was to achieve chemical homogeneity. The mass production of defect-free glass is a relatively recent achievement. It has resulted from better furnaces (Figure 1; Chapters 9.7 and 9.8), higher melting temperatures, and more carefully selected raw materials. In the Chapter 1.2, S. Di Pierro thus discusses the importance of the specifications, sources, and management of raw materials needed to avoid high rejection costs after

melting operations that must be as fast as possible for economic reasons (Chapter 1.2). Being common to most glassmaking processes, fusion itself is then reviewed by R. Conradt from a dual thermodynamic and kinetic standpoint; the account includes not only the fundamental reaction and dissolution steps of the batch ingredients but also the fining and homogenization of the melt produced (Chapter 1.3).

The second part of the section is devoted to the making of three basic products. Flat glass is dealt with by T. Kamihori. He begins with the first mechanical methods devised at the turn of the nineteenth and twentieth centuries, turns to the famous float process, which revolutionized the flat-glass industry in the 1960s, and ends with the recent drawdown processes widely used to produce new glasses for electronic applications with ever stricter quality specifications (Chapter 1.4). Container glass is considered by C. Roos who briefly presents the first forming devices designed at the beginning of the twentieth century before describing the various ways in which a bottle is now shaped with *Individual Section* machines at extremely high rates and may then be protected by treatments such as coating to enhance resistance to breakage (Chapter 1.5). In the next chapter, the drawing of continuous glass fibers for the relatively small but important reinforcement market is considered by H. Li and J. Watson in terms of both processes and composition evolutions driven by the need to improve chemical and physical properties (Chapter 1.6). That computer modeling of glassmaking has become an important tool to save time and money in the design or improvements of plants is explained by P. Prescott and B. Purnode in the final chapter of this section, which shows that, in industry too, fundamental insights and an accurate knowledge of the physical properties of melts have become badly needed (Chapter 1.7).

Other processes and their products are too diverse to be gathered into a common chapter. Hence, they are described along with some of their important applications: the secondary fabrication of flat glass in Chapter 9.2, the making of thermal insulation fibers in Chapter 9.3, of sol-gel products in Chapter 8.2, of glass tubes in Chapter 7.7, and of light bulbs in Chapter 6.9. Other fabrication issues are dealt with in chapters devoted to modern furnaces (Chapters 9.7 and 9.8), cullet recycling (Chapter 9.9), and the history of glassmaking processes (Chapters 10.5, 10.7, and 10.8).

1.1

Glass Production: An Overview

Reinhard Conradt

RWTH Aachen University, Aachen, Germany

1 Introduction

The term “glass” may either refer to a special state of matter in general or to a group of industrially manufactured materials. The chart in Figure 1 presents, from a chemical point of view, an overview of a large number of systems that can be easily transferred into the glassy state. In this chart, special emphasis is given to the industrially relevant group of silicate glasses because, by volume or mass, the vast majority of the glasses produced belong to it. Nonsilicate oxide glasses and other inorganic nonmetallic glasses, nevertheless, play an essential role in the production of highly specialized functional materials such as optical fibers (Chapter 6.4). The group of “other glasses” comprises materials of very different nature. Within this group, metallic glasses (Chapter 7.11) are finding a variety of practical applications whereas organic glasses (Chapters 8.7 and 8.8) have long played a major role at the industrial scale.

No attempt is made here to present a concise definition of the glassy state in general. From a practical point of view, however, glasses comprise a group of noncrystalline homogeneous and isotropic materials characterized by the absence of any microstructure. Thus, in contrast to (poly)crystalline materials, the bulk properties of which are essentially tailored via their microstructure, those of glasses are chiefly designed via their chemical composition; by contrast, thermal treatment has a comparatively small “fine-tuning” effect, which may, nevertheless, become crucial for specific products (e.g. optical or *strong* glasses).

At the atomic scale, the very same bonding interactions are present in isochemical condensed phases, i.e. in liquids, glasses, and crystalline polymorphs. Therefore, the chemical and electronic properties of glasses resemble those of their crystalline counterparts – with the reservation that glasses typically possess larger molar volumes, higher entropies, and higher (less negative) enthalpies of formation. In other words, they are thermodynamically less stable than crystals. Nevertheless, their macroscopic properties reflect in essence the same dependences on chemical composition as their crystalline counterparts. Without mentioning a host of other polymorphs, SiO₂ may, for example, exist under ambient conditions as quartz, cristobalite, or vitreous silica; thermodynamic stability decreases in the given order. The same applies to hydrolytic stability, a macroscopic property for which all SiO₂ polymorphs nonetheless stand out by comparison with other oxides.

In general, information on atomic bond strengths, compound formation energies, and phase equilibria in a system of a given chemical composition may serve as reliable guidelines to explore the relation between the chemical composition of a glass and its macroscopic properties. It would go too far to draw the same conclusion for the relation between the chemical composition and the short-range order structure. Although there is ample experimental proof for such a relation in many systems [1], the general claim may be misleading, even erroneous in specific instances. Yet, in any case, the energetics pertaining to a specific glass structure is in general very close to that of an isochemical crystalline system. Energetics, in turn, is the key factor governing the relation between the chemical composition of a glass and its macroscopic properties. For this reason, equilibrium phase diagrams ([2, 3], Chapter 5.2) and thermochemical databases [4–9] are most helpful tools in the design of glass compositions with desired properties.

Yuanzheng Yue, Aalborg University, Aalborg, Denmark

Figure 1 Glass-forming systems, classified by chemical composition.

The industrial synthesis of glasses can also be based on a large systematic collection of experimental data of the properties of glass-forming systems [10–14]. Because at a microscopic level, atomic interactions are primarily pairwise (Chapter 2.7), one can in particular make use of empirical composition–property relations [15–20] of the type

$$P = \sum a_j \cdot p_j + b_j \cdot p_j^2 + \dots, \quad (1)$$

where P denotes a macroscopic property, p_j is the mol or weight fraction of component j , and the a_j and b_j coefficients are sets of empirical parameters representing the contribution of component j to the property P of the glass.

2 Industrially Manufactured Glasses

2.1 Properties of Manufactured Glasses in General

In addition to the influence of chemical composition, it is the homogeneity, isotropy, and absence of any microstructure that brings about the main features shared by most industrially manufactured glasses. This group of materials stands out from others by

- aesthetics; historically, the fact that glass was looking like gems has been the predominant driving force for the invention of glass as a material (Chapter 10.2). Aesthetic requirements today remain an important aspect, technically expressed as *quality* since, for instance, the presence of a single blister calls for the rejection of a 3×6 m sheet of flat glass.
- its suitability for large-scale continuous primary forming as sheets, rods, tubes, and fibers.
- its extreme variability of shapes in discontinuous forming, comprising shapes with undercut.
- optical transparency. By virtue of their electronic and ionic properties, homogeneity, and absence of any microstructure, most glasses have an excellent transparency in the visible range. A standard float glass (4 mm thick) is transparent for light at wavelengths from 300 to 3500 nm, covering the entire visible (400–760 nm) and the near-IR ranges, the reflection losses of a standard glass sheet remaining slightly lower than 8%.
- an extremely wide and continuous compositional variability. Glasses can also easily incorporate functional components such as colorants.
- an extremely smooth surface, which originally allowed glass not to “smell” the odors of the substances it was storing. Today an as-received float glass possesses a roughness (root mean squared [RMS] value) of approximately 0.5 nm on the atmosphere side, and 1 nm on the tin-bath contact side. Even after an extended exposure to water or humid air at room temperature, RMS remains well below 10 nm. This makes glasses ideal substrates for metal and other functional coatings.
- excellent dielectric properties. Lead silicate glasses used in the back part of cathode-ray tubes reach dielectric constants of 20. It is true, this number does not match the extremely high values of functional ceramics (polycrystalline $\text{TiO}_2 \approx 100$, $\text{BaTiO}_3 \approx 1000$). When it comes to breakthrough voltages, however, the lack of any microstructure confers a clear advantage to glasses over polycrystalline materials: polycrystalline alumina withstands less than 8–9 kV/mm, whereas alkali-free

glasses reach 40 kV/mm, like natural mica; glass ceramics doped with BaTiO₃ crystals may even reach values higher than 400 kV/mm.

- excellent chemical durability against most chemicals. This is especially the case for silicate glasses in the low-pH range (i.e. with strong acids), making them excellent materials for chemical-process plants.
- an extremely high stiffness and intrinsic strength, both again by virtue of the absence of any microstructure. With a tensile strength of up to 4000 MPa (glass fibers), glass ranges among the strongest materials available. Its proverbial fragility is not a matter of strength, but of vulnerability of its surface and of low fracture toughness (Chapter 3.11).

It is a combination of the above features which gives glass such a prominent and indispensable place in the world of materials.

2.2 Classification of Glasses by Commercial Branches

From a technical point of view, glasses are classified in terms of applications rather than chemical composition. The following list presents the most important groups of industrial products under this aspect.

Glass hollowware

Container glass	Bottles (flint, green, amber) Preserving jars Flaconnage
Tableware	Stemware, kitchenware, vases

Flat glass

Architectural glass
Glass for personal security and property protection
Glass for photovoltaic application
Fire-resistant glass
Automotive glass
Decorative interior glass and mirrors

Fiber glass

Continuous fibers (textile; reinforcement)	Multi-purpose (E) Acid resistant (A, C, E-CR) Alkali resistant (AR) High strength (R, S) Dielectric (D)
Fibers for thermal and acoustic insulation	Glasswool, stonewool

Other glass, comprising specialty glass

Soluble glass (water glass)	For chemicals and detergents
Foam glass	For thermal insulation
Laboratory and industry	Lab ware glasses Glasses for process plants Electrode glasses
Artificial lighting	Incandescent lamps Gas-discharge lamps Semiconductor light sources Reflectors
Pharmaceutics and medicine	Ampoules and vials Antibacterial glasses Bioactive glasses
Optics	Eyeglasses Cameras, microscopes, telescopes Fiber optics and endoscopy Telecommunication fibers Laser glasses
Electronics and energy generation	Electronic tubes Sealing glasses Soldering and passivation glasses Substrate glasses and display glasses Glasses for thermal power generation
Radiation protection	Radiation shielding windows High-energy radiation detection windows
Silica ("quartz") glass	For high-T processing For silicon crystal growth For silicon-wafer handling For optical fibers

The pie chart in Figure 2 provides a rough overview of the shares of these categories by amounts of worldwide production. The figures given are estimates based on an evaluation of multiple sources for the time span 2003–2008. By absolute amounts, the 2005 world production reached about 124 million metric tons (31 in the European Union, 8 in Germany). Since then, an average annual increase of about 3.5% is observed. Whereas the production is more or less leveling off in most industrialized countries, the PR of China is among the main

driving markets for this increase as its 2005 output of flat glass already accounted for more than 50% of the world production (cf. Chapter 9.6).

For each type of glass products listed above, a typical chemical composition range has been adopted world-wide. The compositions of container and flat glass have never been developed by a scientific approach. Rather, they have remained pretty the same ever since the beginnings of glass makings (Chapter 10.2). Compositions have thus been very early constrained by the availability of affordable raw materials, the need to prevent water corrosion, and the highest temperatures reached in furnaces.

A systematic scientific approach to glass compositions did not begin before the nineteenth century, chiefly promoted by the work of individuals such as Fraunhofer,

Faraday, Harcourt, Abbé, or Schott (Chapter 10.11). Since then, this scientific approach has remained the basis for designing not only the compositions of most specialty glasses but also to improve those of existing products. For example, there is a quest among the producers of continuous fibers for completely new compositions with outstanding mechanical or chemical properties such as high modulus for lightweight construction composites or extreme alkali resistance for concrete reinforcement. In other cases, the driving force for development stems from environmental or health concerns and legislation. As examples, lead and arsenic oxides are being replaced in the formulae of optical glasses, solder and sealant glasses, and even in crystal tableware, whereas insulation-fiber compositions have been reformulated to avoid any confusion with asbestos fibers whose cancerogenic potency is well known. The typical composition ranges of current glass products are summarized in Table 1.

Figure 2 Glass production by branches; figures in % in the sequence world/United States/Europe.

3 Process-controlling Properties

3.1 Viscosity

Among all the properties of a glass-forming substance, the viscosity–temperature relationship is by far the most important practically in glass making. Referring to Chapter 4.1 for an in-depth review of this topic, here we will consider it from a simpler technological point of view. The main feature then is that the viscosity of a glass-forming liquid extends over a range of 12–14 orders of magnitude, which thus involves large rheology changes in the temperature range relevant to glass manufacturing

Table 1 Typical compositions of industrial glasses comprising main oxides only (no colorants or impurities); compositional ranges from multiple sources (e.g. [13]) or typical individual examples (wt %).

Oxide	Container glass	Float glass	Crystal glass	Display glass	E fiber glass	Glass wool	Stonewool	Low- α glass	Soluble glass
SiO ₂	66–75	70–74	66.0	65.0	52–60	56–66	35–48	70–81	66–77
TiO ₂			1.0				0–3		
Al ₂ O ₃	1–3	0.5–1.5	2.0	18.0	12–16	0–6	12–28	2.5–5	
Fe ₂ O ₃							3–12		
B ₂ O ₃				1.0	0–9	3–9		10–15	
MgO	0–4	0–4	4.0	7.0	0.5–4.5	1–5	2–11	1.0	
CaO	8–12	7–10	6.0	6.0	16–24	5–11	10–28	1.0	
BaO			2.0	3.0					
ZnO			3.0						
Li ₂ O	0–1							0–1	
Na ₂ O	11–15	12–14	8.0		0–2	13–17	1–6	4–8	23–34
K ₂ O	0–2	0–1				0–2	1–6	0–3	

Table 2 Viscosity ranges of industrially manufactured glasses.

Viscosity as log η , η in dPa·s	Process range, technological meaning ^a
Melting	
2.0	Typical of a soda-lime silicate glass melt at 1450 °C
3.0	Transfer to forming area Volume relaxation time is <1 s Fixpoint $T(3.0)$ = gob temperature Bushing tip temperature for fiber production ^b
Forming	
4.0.	Upper limit of mechanical working range Fixpoint $T_{WP} = T(4.0)$ = working point
6.0	Lower limit of mechanical working range The difference $T(4.0) - T(6.0)$ is termed the “length” of a glass
Tempering, annealing, and cooling	
7.6	Upper limit of macroscopic shape stability Fixpoint $T_L = T(7.6)$ = Littleton softening point
11.0 ^c	Dilatometric softening point T_D Above T_D , temperature gradients in a glass object no longer cause thermal stresses A related temperature level is $T_d = T(11.5)$ = deformation point Glass objects deform under own weight at rates of a few $\mu\text{m/h}$
13.0	Technical definition of the glass transition Fixpoint $T_g = T(13.0)$ = annealing point Volume strain relaxation time is 60 s
14.5	Technical definition of ultimate transition to a rigid state Fixpoint $T(14.5)$ = strain point Volume strain relaxation time is 30 min

^a In the earlier days of mechanical forming, empirical indicators were in use. They remain worth to be consulted as empirical guidelines when the complex feature of “workability” is to be kept constant under a compositional change; these indicators read: gob temperature, $GT = 2.63 \cdot (T_L - T_g) + T_L$; working range index $WRI = T_L - T_g$; RMS = relative machine speed = $(T_L - 450)/(WRI + 80)$; DI = devitrification index = $WRI - 160$.

^b Some stonewool processes use $T(1.5)$ as fibrization temperature.

^c Approximation, the exact value depending on the load applied by the dilatometer.

(Table 2). Conventionally, technologists do not report viscosities in terms of values found at given temperatures, but rather in terms of temperatures at which given viscosity values are obtained. Thus, $T(n.n)$, the *isokom* temperature, denotes the temperature in °C at which the melt assumes a value $\log \eta = n.n$ in poise CGS units (1 P = 0.1 Pa·s so that all values compiled in Table 1 have to be decreased by 1 if one retains instead the Pa·s SI unit used in many recent publications). The importance of reporting temperatures instead of viscosities rests on the facts that the (Newtonian) rheological response of all substances is by definition the same at the same viscosity and that only the temperature of a glass – not its viscosity – can be operationally regulated during the various forming, tempering, annealing, or cooling steps of glass making.

Viscosity–temperature relationships do vary much with chemical composition: as illustrated in Figure 3 by the data for a soda-lime float glass, a stonewool and silica

Figure 3 Viscosity–temperature relationship of different glass-forming systems; pure metallic melts of Ag and Fe are displayed for comparison.

glass, and those for a bulk metallic glass and pure Ag and Fe liquids. The fixed points of Table 1 are pinpointed for each glass melt and read in this graph, as just explained, starting from its Y axis. The complete viscosity curves can be reproduced by Vogel–Fulcher–Tamman (VFT) equations,

$$\log \eta = A + B/(T - T_0), \quad (2)$$

where A , B , and T_0 are empirical fit constants and T is expressed here in $^{\circ}\text{C}$. The float glass DGG-1 included in Figure 3 is a certified viscosity standard whose VFT equation has been derived from 44 measurement points. These are reproduced with the parameters $A = -1.601$, $B = 4330.9$, and $T_0 = 246.1$ (η in dPa·s) with a standard deviation of $\delta \log \eta = \pm 0.16$, illustrating that the VFT equation is a valuable tool for any technological purpose.

Viscosities are in addition an indicator of crystallization tendency at the liquidus temperature T_{liq} , which is shown in Figure 3 on the viscosity curves. Melts with $\log \eta(T_{\text{liq}}) < 2.0$ tend to crystallize quickly, thus requiring very high cooling rates, whereas melts with $\eta(T_{\text{liq}}) > 4.0$ may in contrast be vitrified at moderately low cooling rates.

Of great interest, therefore, is the possibility to predict the viscosity of a glass melt as a function of its temperature

and chemical composition. From measurements performed for a variety of samples, sets of incremental factors have been empirically derived by regression analysis for this purpose. The left-hand part of Table 3 presents such a widely used database [19] with which the effect of additions of individual oxides (by weight and molar amounts, respectively) have been calculated for a soda-lime silicate. The temperature $T(\text{n.n})$ at which viscosity reaches $10^{\text{n.n}}$ dPa·s is thus calculated as

$$T(\text{n.n}) = a(\text{SiO}_2) + 100 \cdot \sum a(j) \cdot y(j)/y(\text{SiO}_2), \quad (3)$$

where $y(j)$ is the weight fraction of oxide j .

Helpful guidelines for the design of the viscosity curve of a mass-produced glass may be derived from the graphs of Figure 4. For example, replacement of 1 wt % SiO_2 by 1 wt % Li_2O to yield a glass 73 wt % SiO_2 , 10 CaO, 16 Na_2O , 1 Li_2O lowers the temperature at $\log \eta = 4.0$ and 13.0, relative to the base glass, by 45 and 29 K, respectively. Among the *alkali oxides*, lithia is the strongest liquidus flux; it significantly lowers viscosity at all levels. *Boron oxide* has a similarly strong effect, however, at high-temperature only. So it reduces the working range (the

Table 3 Empirical factors for the calculation of viscosities [19] and elastic properties [21, 22] (units revisited) from composition.

Oxide j	Viscosity				Elastic properties	
	$a(j)$ for			Validity range (wt %)	$V(j)$ (cm^3/mol)	$U(j)$ (GPa)
	$T(2.0)$ ($^{\circ}\text{C}$)	$T(4.0)$ ($^{\circ}\text{C}$)	$T(6.0)$ ($^{\circ}\text{C}$)			
SiO_2	1847.80	1249.70	962.90	60–77 ^a	28.0	64.5

CaO	−11.27	−3.99	−0.74	4–13 ^a	18.8	64.9
BaO	−5.67	−3.04	−1.88	0–17 ^b	26.2	40.6
ZnO	−5.37	−1.99	−0.71	0–9 ^b	15.8	41.5
PbO	−4.85	−3.17	−2.24	0–12 ^b	23.4	17.6
Li_2O	−35.54	−30.04	−26.45	0–3 ^a	16.0	80.4
Na_2O	−12.65	−9.19	−7.06	10–17 ^a	22.4	37.3
K_2O	−5.93	−4.17	−3.53	0–9 ^a	37.6	23.4
Error	± 4.7 K	± 3.4 K	± 3.2 K	—	n.s.	n.s.

^a Combinations of these oxides, plus one.

^b Oxide only, keep the error within the given $\pm$ range.

^c For boron oxide, the factors in the second row are square terms; thus, the sum for each $T(\text{n.n})$ has to be expanded by a term $10\,000 \cdot a(\text{B}_2\text{O}_3) \cdot [y(\text{B}_2\text{O}_3)/y(\text{SiO}_2)]^2$.

Figure 4 Temperature change brought about by a replacement of 1% of SiO_2 by another oxide in the base glass composition 74 SiO_2 , 10 CaO , 16 Na_2O ; left side: for oxide amounts by wt; right side: for molar amounts.

“length”) of a glass. In the language of glass technologists, boron oxide makes a glass “short.” Lime strongly reduces viscosity at high temperatures; the effect is almost as strong as with soda. Thus, if viscosity needs to be lowered in this range, inexpensive limestone as a calcium carrier raw material may be used instead of expensive soda ash as a sodium carrier. Also note that lime, quite in contrast to *magnesia*, makes a glass “short.” One can thus extend the working range of a glass by manipulating its CaO/MgO ratio. *Alumina* makes at the same time a glass more viscous and “longer.” Although not giving any in-depth scientific understanding, these empirical tools undoubtedly have their merits in glass technology.

3.2 Liquidus Temperatures

Most industrial glass-melting processes run in a continuous way 365 days per year over periods of 2–15 years. This operation time depends on the type of glass and on the corrosion wear of both the refractory lining of the melting tank and channels guiding the melt to the working stations. A maximum temperature of about 1500 °C is needed to achieve homogenous fusion; at the exit of the furnace, the melt still is at about 1350 °C. This temperature makes it necessary to cool steadily the melt down to $T(3.0)$ while keeping a safety margin ΔT above the liquidus temperature T_{liq} of the particular composition to prevent precipitation of crystals. This

yields a constraint of a minimum temperature of $T(3.0) + \Delta T$ required to ensure a crystal-free glass. This constraint is especially critical for continuous glass fiber production (Chapter 1.5), but it applies to any other process as well before the forming step.

Traditionally, liquidus temperatures have been determined experimentally to be represented graphically for simple-enough systems in the form of phase diagrams (Chapter 5.2, [2]). For complex compositions of industrial interest, they are generally determined with a gradient furnace whereby a series of 5–10 samples are heated for typically 24 hours in a temperature gradient spanning the expected range of T_{liq} . After quenching, the samples are examined by optical microscopy. The liquidus temperature is then bracketed by the treatment temperatures of the last homogeneous glass and that of the first sample in which crystallites are observed. In a more accurate approach, samples from the gradient furnace containing tiny amounts of crystals are reheated in a heating-stage microscope at a rate well below 1 K/min, and the temperature at which the last crystal dissolves is adopted as T_{liq} .

Thanks to the progress made in thermodynamic modeling of melts (Chapter 5.3), an increasingly useful approach is to predict liquidus temperatures with one of the dedicated softwares designed to calculate phase equilibria relevant to glass making (e.g. 20). Empirically, however, simple rules have long been known to predict

the effects on a given oxide on liquidus temperatures. Illustrating again the predominantly pairwise nature of atomic interactions, they rely particularly on the topology of binary phase diagrams (Figure 5). The tremendous freezing-point depressions of SiO_2 brought about by addition of alkali oxides as well as by boron and lead oxides are in fact so conspicuous that they have historically been at the basis of the development of glass technology. As illustrated by a comparison made between Li_2O and K_2O (Figures 4 and 5), of particular interest is the fact that

the alkali oxide that most strongly decreases viscosity is the least effective in lowering liquidus. Only boron and lead oxides cause strong decreases of both viscosity and liquidus. This may shed some light on the technological challenge raised by the replacement of lead oxide in the glass formulae of modern tableware and solder glasses.

In ternary systems, the Na_2O – CaO – SiO_2 and CaO – Al_2O_3 – SiO_2 phase diagrams are especially important as they serve as references for soda-lime and most stoneware and reinforcement-fiber glasses, respectively (Figure 6).

Figure 5 Liquidus lines of binary silicate systems (left: by wt, right: by mol); all systems comprising a divalent oxide, except BaO, show an extended stable miscibility gap; data source [2].

Figure 6 Ternary phase diagrams in versions of technological relevance; shorthand notation: N = Na_2O , C = CaO , A = Al_2O_3 , S = SiO_2 , Q = quartz, TR = tridymite, CR = cristobalite; left: the basic system of all commercial hollowware and flat glasses; the triangles mark the positions of the compounds, $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$; the circle the position of the base glass 74 SiO_2 , 10 CaO , 16 Na_2O ; data source [2]. Right: the basic system of reinforcement-fiber glasses; industrial compositions flock around the eutectic; calculation using FactSage® [23].

Figure 7 Miscibility gaps. (a) Extension of stable gaps in ternary borosilicate systems with different oxides as third component; the area shaded in gray refers to BaO; (b) isotherms of the (metastable) subliquidus immiscibility dome in the system $\text{Na}_2\text{O}-\text{B}_2\text{O}_3-\text{SiO}_2$.

From Figure 6a, it is easy to understand why, in Antiquity (Chapter 10.3), glasses with silica contents of 70–74 wt % and amounts of lime not exceeding 12 wt % were already mass produced: Thanks to typical $T(3.0)$ values of $1200 \pm 10^\circ\text{C}$, it is comparatively easy to comply for them with the constraint $T_{\min} = T(3.0) + \Delta T$. The particular composition “16-10-74” has been investigated in many scientific studies. It may be considered as a reference and the *mother* of all mass-produced glasses, including of course today’s float glass. That the $T_{\min}$ constraint represents in contrast a real challenge for $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ -based glasses is readily apparent in Figure 6b where only a narrow range around the ternary eutectic between tridymite [SiO_2], wollastonite [CaSiO_3], and anorthite [$\text{CaAl}_2\text{Si}_2\text{O}_8$] qualifies for a successful production. In passing, note that Figure 6b has been calculated by using the thermochemical software and databases FactSage® [23]. The experimental position of the mentioned eutectic is also marked, thus displaying the degree of accuracy that may be expected from the calculation of liquidus for more complex compositions.

3.3 Liquid–liquid unmixing

If phase separation within a condensed system most commonly takes place via partial crystallization, it can also occur as liquid–liquid unmixing (Chapter 5.2). Ternary systems containing boron oxide illustrate that the phenomenon should certainly not be overlooked in glass-forming systems. For ternary borosilicates, the boundaries of the composition domains where such an unmixing

takes place stably, i.e. above the liquidus, are indicated in Figure 7a. If temperature is represented in a third dimension, these domains define the base areas of immiscibility domes that eventually terminate at upper critical points at their tops. The isotherms of the immiscibility dome in the system $\text{Na}_2\text{O}-\text{B}_2\text{O}_3-\text{SiO}_2$, which is the base composition of all borosilicate glasses, are drawn in Figure 7b. Here, in contrast to Figure 7a, the entire dome comprising its upper critical point (755°C at composition 25-05-70 by wt) is located below the liquidus surface. Hence, liquid unmixing cannot take place during the initial melting step, but at lower temperatures during the forming process. This is one of the reasons why, in order to minimize phase-separation effects, pharmaceutical and low-expansion borosilicate glasses are designed around a composition of 80 wt % silica. The system $\text{Li}_2\text{O}-\text{B}_2\text{O}_3-\text{SiO}_2$ (not shown here) displays a similar topology.

It is only with glasses known under the trade name *Vycor Glass* that liquid unmixing is exploited on purpose. Here, after forming by conventional technology to the desired shape, phase separation develops upon annealing at an appropriate temperature to yield two interconnected phases, namely an Na_2O - and B_2O_3 -rich glass along with another one that contains more than 96 wt % SiO_2 . Then the former is leached out by a hot strong mineral acid, leaving behind a nanoporous skeleton of high- SiO_2 glass. This material may then be used directly as filter, for example, or sintered at temperatures below 1300°C to fabricate dense and almost pure silica glass articles much more readily than with pure SiO_2 .

The numerical calculation of liquid–liquid immiscibility ranges in multicomponent systems (e.g. by using the software and databases mentioned in Section 3.2) is even more challenging than the calculation of solid–liquid equilibria. This is because available experimental data hardly reach beyond what has been sketched in the present section, and such a narrow base of information does not allow to fine-tune the parameters used in the calculations.

4 Glass Composition – its Relevance to Glass Properties

4.1 Property Optimization

Both search and optimization of glass formulae begin with a given profile of target glass properties. In the following, three properties will be addressed as examples typically targeted in glass development, namely the elastic properties, the thermal expansion coefficient, and the chemical durability. From a scientific point of view, such a task should rest on deep insights on the relationships between chemical composition, glass structure, and glass properties. It is only from such a fundamental approach that ground-breaking developments of novel glasses with outstanding properties may be expected. But this goal is still a matter of fundamental research as expounded in the following chapters where this most challenging issue is pursued.

For the time being, however, only few manageable tools and procedures of this kind are available for the technological community. To optimize properties, technologists thus rely largely on empirical approaches whereby, as applied to glass viscosity in Section 3.1, they use incremental oxide factors derived by statistical means from large numbers of experiments. One has, however, to keep in mind that these approaches represent only interpolations of what is already known. Hence, limited areas in compositional space leading to truly outstanding properties should be easily overlooked so that developments similar to the famous low-expansion metallic alloy *Invar* are very unlikely to be found this way.

4.2 Elastic Properties

Incremental oxide factors for the calculation of the elastic properties from the composition compiled in the right-hand part of Table 3 are taken from a widely accepted earlier publication [21]; for the sake of clarity, they have been adjusted with respect to the units used, i.e. to cm^3/mol for volume, and to GPa for modulus increments. Young's modulus E is then calculated with

Figure 8 Change of Young's modulus E in the base glass composition 74 SiO_2 10 CaO $16 \text{ Na}_2\text{O}$ upon the replacement of x wt % silica by another oxide.

$$E = [\rho \cdot \sum V(j) \cdot x(j) / \sum M(j) \cdot x(j)] \cdot \sum U(j) \cdot x(j), \quad (4)$$

where $x(j)$ and $M(j)$ are the mole fraction and molar mass of oxide j , respectively, and ρ the density of the glass.

As for Poisson's ratio μ , it is calculated as

$$\mu = 0.5 - 0.278 / [\rho \cdot \sum V(j) \cdot x(j) / \sum M(j) \cdot x(j)]. \quad (5)$$

The manner in which Young's modulus varies when a glass composition of $(74 - x)\text{SiO}_2$, 10 CO , $16 \text{ Na}_2\text{O}$ (by wt) is modified by an addition of x wt % of another oxide is illustrated in Figure 8. Young's modulus can be raised by the addition of P, Li, B, Zr, Mg, and Al oxides, and in contrast lowered by oxides of heavy mono- and divalent ion oxides. True, such small additions do not yield major overall effects but the tendency is clearly shown.

4.3 Thermal Expansion Coefficient

Incremental oxide factors for the calculation of the thermal expansion coefficient are compiled in Table 4. Again, the factors are taken from a widely accepted earlier publication [24], see also [15]. When inspecting the entries in Table 4, the reader will notice a number of conditions that have to be obeyed for specific compositions. These conditions reflect intrinsic structural changes, which

Table 4 Empirical factors for the calculation of the thermal expansion coefficient α_{20-300} in ppm/K; it is calculated from the molar fractions of oxides j like $\alpha_{20-300} = \sum x(j) \cdot \alpha(j)$.

Oxide j	Increment $\alpha(j)$	Condition
SiO ₂	10.5–10· $x(\text{SiO}_2)$	$x(\text{SiO}_2) > 0.67$
	3.8	Otherwise
TiO ₂	10.5–15· $x(\text{SiO}_2)$	$0.5 < x(\text{SiO}_2) < 0.8$
ZrO ₂	–6.0

	39.5	Otherwise
K ₂ O	46.5	in K ₂ O–SiO ₂
	42.0	Otherwise

$\varphi = (\text{Na}_2\text{O} + \text{K}_2\text{O} + \text{BaO} + 0.7 \cdot \text{CaO} + 0.7 \cdot \text{PbO} + 0.3 \cdot \text{Li}_2\text{O} + 0.3 \cdot \text{MgO} + 0.3 \cdot \text{ZnO} - \text{Al}_2\text{O}_3) / \text{B}_2\text{O}_3$;

$\psi = \sum (\text{RO} + \text{R}_2\text{O}_3 + \text{R}_2\text{O}_5)$;

Oxide amounts to be inserted as molar fractions.

can be understood only if the chapters in Part II are consulted. As an example, the sophisticated condition for the increment of boron oxide by the factor φ reflects the expected coordination change between $[\text{BO}_3]$ and $[\text{BO}_4]$ units in the glass (Chapter 7.6). Predictions based on these factors yield estimates of the thermal expansion coefficient within an error margin of ± 0.3 ppm/K. The effect of addition of x wt % of another oxide is shown in Figure 9 for the base glass composition 74 SiO₂·10 CaO·(16– x) Na₂O. Clearly, alkali oxides raise the thermal expansion coefficient whereas especially oxides of highly charged ions decrease it. Iso lines of the expansion coefficient within the ternary sodium borosilicate system are plotted in Figure 10. Optional compositions for so-called “hard” glasses with $\alpha = 4$ ppm/K are marked. The base composition 6 Na₂O·10 B₂O₃·84 SiO₂ may be considered as a starting point for further adjustment. When taking $6 \text{ Na}_2\text{O} \rightarrow 4 \text{ Na}_2\text{O}$, $10 \text{ B}_2\text{O}_3 \rightarrow 13 \text{ B}_2\text{O}_3$, $84 \text{ SiO}_2 \rightarrow 81 \text{ SiO}_2 + 2 \text{ Al}_2\text{O}_3$, then the composition obtained is

Figure 9 Change of the thermal expansion coefficient α_{20-300} in the base glass composition 74 SiO₂ 10 CaO 16 Na₂O upon the replacement of x wt % of calcia by another oxide.

Figure 10 Ternary composition diagram of the system Na₂O–B₂O₃–SiO₂ showing iso lines of the thermal expansion coefficient α_{20-300} ; base glass compositions reaching coefficient $\alpha_{20-300} = 4.0$ ppm/K are highlighted; the further development strategy toward an industrial product is sketched in the upper right corner and indicated by the arrow.

Figure 11 Hydrolytic stability of different pure oxides in aqueous solution as a function of pH; the stability is given in terms of Gibbs energy of hydration ΔG_{hydr} ; negative values of ΔG_{hydr} are plotted against pH to make the most stable cases appear at the bottom of the graphs.

indeed very similar to those of the commercial products *Duran* or *Pyrex* having a thermal coefficient of expansion $\alpha_{20-300} = 3.3 \text{ ppm/K}$ between 20 and 300 °C.

4.4 Chemical Durability

Chemical durability is a very complex property. Attempts at generating an oxide increment system for the prediction of this property are not recommended because the most basic information on chemical durability must reflect the stability of a glass in strong acids, neutral water, and strong caustic solutions. Irrespective of their role in the glass structure, even pure oxides exhibit quite a complicated stability pattern as a function of the solution pH. This is shown in Figure 11 (from [25], revised version). Clearly, a general statement like “alumina enhances the chemical durability of a glass” is erroneous. It is true, alumina enhances the chemical durability under moderately acid to fairly caustic conditions, but it destabilizes a glass exposed to strong acids. Anyway, Figure 11 provides a first guideline of the effect which may be expected from a specific oxide in a given pH range, and hence, to base a first step of development on this information. In Chapter 5.11, the approach is further elaborated.

5 Perspectives

Challenges for future development mainly deal with the extension of both thermochemical and thermophysical databases for glass-forming systems. The usefulness of phase diagrams and of thermochemical calculations for glass development has been demonstrated. Yet, when it comes to the databases on which the calculations of phase diagrams rest, a severe lack of results for multicomponent melts relevant to the glass industry is felt. This situation is

due to the fact that the extension of databases is chiefly driven by the financially potent metallurgical industry whose compositional focus distinctly differs from the needs of the glass industry. A reliable approach to liquidus temperatures, even for the conventional container, float, or fiber glass branches, would open doors for significant process improvements, resulting in enhanced sand dissolution upon melting, higher pull rates, energy saving, enhanced glass quality, and reduced loss of expensive glass contact materials like platinum.

Whereas thermochemical data sets (standard enthalpies and entropies, C_p polynomials) are available for about 6000 mineral substances, thermophysical standard data sets (including stiffness parameters, and their temperature coefficients) hardly exceed a number of a few hundreds only [26]. From such data, glass technologists might learn how the local atomic structure of a material in general influences the resulting mechanical properties. Thus, to date, the intense quest for stronger glasses rests on an extremely narrow scientific basis. The same is true for the adjustment of the thermal expansion coefficient of solder glasses and substrate glasses to contact materials with very high or very low thermal expansion coefficient (like copper, alumina, steel, or silica glass, low-expansion glass ceramics, respectively).

As stated above, as useful as the conventional oxide increment systems may be in the daily routine of industrial glass development, an approach to truly novel glass compositions with outstanding properties must be based on a deep understanding of the relation between chemical composition, structure, and properties. This is where the field of atomistic simulation should play a decisive role in a near future (cf. Chapters 2.7 and 2.8). The challenge for the coming decades thus consists in developing first-principles tools suitable for industrial applications.

Beyond this, new glass-forming systems with a high potential for application as functional materials are being developed. As described in Chapter 8.9, an important group with relevance at the industrial scale (not shown in the scheme of Figure 1) are hybrid glasses combining both inorganic and organic bonds in their structure. Such glasses have been synthesized via a sol–gel route for a long time (Chapter 8.2); recently, systems accessible by melting have been presented [27].

1.2

Raw Materials for Glassmaking: Properties and Constraints

Simonpietro Di Pierro

EMC2 Department, Saint-Gobain Research Paris, Aubervilliers, France

1 Introduction

Even though industrial glasses may now be transported across the planet, glassmaking tends to remain a local industry. When selecting their raw materials, glassmakers target specific oxides or elements to fit quantitatively a calculated recipe [1, 2] by paying special attention not only to their composition and quality but, of course, also to their price. Raw materials in effect may represent up to one third of the total cost of glassmaking, strongly depending on local geographical and logistic conditions such as quarry-to-plant distance or transportation mode, which can be by waterways, rail, or truck. This concern holds especially true for commodity products which, like hollow ware, are facing fierce competition from metal or plastic materials.

Natural materials are in principle favored because, like for the mineral resources used in metallurgy or cement industry, their extraction, milling, and transportation are relatively inexpensive operations compared to the fabrication cost of synthetic materials. Some of the raw materials used in glassmaking must nonetheless be man-made when their natural counterparts are rare, geographically restrained, or of an insufficient purity. As such, their price can dramatically increase the overall batch cost. For instance, synthetic sodium carbonate may constitute up to 50 % of the total batch cost for window or bottle glass, whereas it constitutes less than 14 wt % of the recipe.

After batch preparation, melting and subsequent chemical homogenization are complex processes whose kinetics depend on a number of factors. The grain size distribution of raw materials is particularly important in this respect as the main starting product, quartz, dissolves into the forming melt at a rate of only a few hundred μm per hour, so that pull rates tremendously decrease with increasing grain size. The impurity content is another fundamental issue. As natural products, most raw materials are far from being pure chemicals. The infusible minerals they may bring in have a very high likelihood of surviving the glassmaking process and, therefore, of causing unacceptable production losses even when present at the ppb levels. Other impurities such as iron metal originate in the initial processing of the raw materials. In any case, impurities may cause raw materials to depart from the specified physical and chemical properties. Production yield and quality can then be strongly impacted.

Since many parameters may have either positive or negative consequences if not properly mastered, an in-depth knowledge of the chemical and physical properties of raw materials is necessary. In this chapter, the main chemical, physical, engineering, and economic criteria pertaining to raw materials specifications will thus be reviewed. Because high production yields cannot be obtained without high-quality and permanently controlled raw materials, attention will be paid to production problems most commonly met if the specifications and management of raw materials are not respected. The focus will be here on the raw materials used for silicate glasses manufactured in very large quantities. For specialty glasses, the reader is referred to the chapters that deal specifically with optical fibers (Chapter 6.4), chalcogenide (Chapter 6.5) or metallic glasses (Chapter 7.10), sol-gel products (Chapter 8.2), or bioglass (Chapter 8.4).

2 Raw-material Specifications

2.1 The Specificity of Raw Materials

A very great many different raw materials can be used today for batch preparation (Table 1). On a chemical and mineralogical basis, they can be classified as silicates, carbonates, borates, oxides, and hydroxides. Recycled glass, known as *cullet* (cf. Chapter 9.9), as well as industrial by-products such as metallurgical slags can in addition enter the batch preparation as amorphous and chemically complex materials. As apparent in Figure 1, the compositions of these materials do not match those of the main glass products, which may thus need up to a dozen ingredients for batch preparation. Even the most common soda-lime silica glasses, circled in Figure 1, manufactured for building (windows), automotive (windshields), packaging (bottles), and solar (photo-voltaic panels) applications, require several of them.

Each raw material plays a specific role. Most of them, as oxides, form the building blocks of the glass network as formers or modifiers (see Chapters 20.4 and 2.5), but among the latter some act as fluxes (alkalis), strengthening agents (alkaline earths), refiners (Na sulfate, Sb, Sn, As oxides), reducers (coke, slags), or even as oxidizing, O_2 -releasing ($BaNO_3$), or coloring (Fe, Cr, Mn, Co, etc.) agents.

Raw materials react in specific ways within the batch. Some are strongly hygroscopic, influencing as such the rheology and homogeneity of the still solid batch. As a matter of fact, water is present in most of the raw materials used to produce glass as either free water (moisture) or bound in the crystal structure of minerals. This essential and unavoidable component is crucial in raw-material management since it minimizes the formation of dust at both the batch plant and the dog-house (entrance of the furnace) levels, but it may also contribute to the formation of lumps made of the most hygroscopic materials, increasing the heterogeneity of the batch at the very beginning of melting. Furthermore, as a result, the batch may contain up to few wt % of water, whereas there are less than 1000 ppm H_2O in the final glass. Removing the water in excess may cost much in terms of both energy and furnace refractories, which may be corroded by acids such as HF and HCl formed when water reacts with other volatile components of the batch.

Without taking into account the formation of intermediate products, the overall meltability of the raw materials is highly variable [3]: H_2O is released at around 100 °C; the deshydroxilation of OH-bearing minerals takes place at 400–800 °C; carbonates release large quantities of CO_2 at 700–900 °C; feldspars melt below 1200 °C; the other

silicates are dissolved in the pre-existing glass melt above that range; bauxite has an even stronger refractory character, needing temperature above 1300 °C to be digested by the surrounding liquid (cf. the DSC thermogram of Figure 3, in Chapter. 1.5).

Suppliers of raw materials process their products through several steps to match their customers' specifications [4]. First, rocks containing the desired raw material(s) are blasted or excavated. The bulk material so extracted is then retrieved, crushed, ground, screened, and sorted to achieve the required grain size, washed, dried, or dewatered before being stockpiled and transported in big bags or in bulk. In some cases a physical and/or chemical beneficiation stage may be needed to achieve the required specifications, especially to remove unwanted impurities. All these steps can have an impact on the final quality of the raw materials in terms of presence of impurities and heterogeneities.

2.2 Grain Size

The particle (or grain) size distribution (PSD) is a crucial parameter of individual raw materials. The required PSD may be costly to achieve. It primarily depends on the hardness of the bulk material, which in turn roughly correlates with its melting temperature [5]. As examples, K-feldspar has a hardness of 6 (out of a maximum of 10) on the Mohs scale and melts at about 1200 °C, quartz has a hardness of 7 and melts above 1700 °C (in the form of cristobalite), whereas corundum ($\alpha-Al_2O_3$) has a hardness of 9 and melts above 2000 °C. Hence, the glassmaker determines the final PSD of the raw material as a compromise between meltability, furnace technology, and price (cost) while also limiting the unnecessary fines that generate dust and furnace carryovers. For specific applications, the glassmaker may in addition request the supplier of raw material to cut the lower end of the PSD to get totally rid of dust from fines.

The sieve PSD curves of a variety of important raw materials are compared in Figure 2 to illustrate their variations with composition and overall batch meltability. The median diameter representing 50% of a sieved raw material is termed D50. For quartz, it ranges from 200 to 300 μm when sand is used for standard window or bottle glass but is much lower at 50–100 μm for the flour, for instance, used as SiO_2 -carrier for E-glass fiber, a peraluminous, boron-bearing, alkaline earth silicate (Chapter 1.5). At the other end, the D50 of limestone and dolomite may exceed 1 mm and that of basalt for insulating glass applications may even be 10 times larger because chemical heterogeneities are in this case much smaller than within a mixture of raw materials.

Table 1 Natural and *synthetic* raw materials compositions and prices.

Oxide	Raw material	Bulk chemistry	Overall mineralogy	Sp – Fr – It – De	Price €/T*
SiO ₂	Quartz-sand	>95 % SiO ₂ ; H ₂ O, Al ₂ O ₃ , RO, R ₂ O, Fe ₂ O ₃	Quartz, free-water, mica, feldspars	Arena – Sable – Sabbia – Sand	20–200€/T
	Sandstone	>95 % SiO ₂ ; H ₂ O, Al ₂ O ₃ , RO, R ₂ O, Fe ₂ O ₃	Quartz, mica, feldspars, FeTi-oxides, free-water	Arenisca – Grès – Arenaria – Sandstein	
	Quartzite	>95 % SiO ₂ ; H ₂ O, Al ₂ O ₃ , RO, R ₂ O, Fe ₂ O ₃	Quartz, mica, feldspars, FeTi-oxides	Cuarcita – Quartzite – Quarzite – Quarzit	
Al ₂ O ₃ , R ₂ O	Feldspar (concentrates from greywacke, arkose, pegmatite, granite, etc.)	17–20 % Al ₂ O ₃ ; 11–15 % R ₂ O; <65 % SiO ₂ ; H ₂ O; Fe ₂ O ₃ , TiO ₂ , CaO	Alkali-feldspars [(K,Na)AlSi ₃ O ₈ : orthoclase, microcline, sanidine, albite, and their solid solutions], quartz (15–20%), micas. Li-rich (up to 1.5 wt %) contain spodumene, petalite, or lepidolite (Li-mica), mainly.	Feldespato – Feldspath – Feldspato – Feldspat	80–150€/T
	Nepheline(–syenite)	20–26 % Al ₂ O ₃ ; 15–18 % R ₂ O; <56 % SiO ₂ ; H ₂ O; Fe ₂ O ₃ , TiO ₂ , CaO	Alkali-feldspars [(K,Na)AlSi ₃ O ₈ : microcline, sanidine, albite, and their solid solutions], alkali-feldspatoids [(K,Na)AlSiO ₄ : nepheline, kalsilite, and their solid solutions], micas, titanite, perovskite, garnet, zircon, apatite, REE-silicates. Silica undersaturated = no quartz	Nefelina – Néphéline – Nefelina – Nephelin	100–130€/T
	Phonolite	20–26 % Al ₂ O ₃ ; 15–18 % R ₂ O; <56 % SiO ₂ ; H ₂ O; Fe ₂ O ₃ , TiO ₂ , CaO	Alkali-feldspars [(K,Na)AlSi ₃ O ₈ : sanidine, albite, and their solid,solutions], alkali-feldspatoids [(K,Na)AlSiO ₄ : nepheline, kalsilite, and their solid,solutions], leucite KAlSi ₂ O ₆ , sodalite, haiüyne, carnegeite, micas, amphibole, pyroxene, titanite, ilmenite, perovskite. Silica undersaturated = no quartz	Fonolita – Phonolite – Fonolite – Phonolith	60–70€/T
	Anorthosite	<30 % Al ₂ O ₃ , <15 % CaO, <45 % SiO ₂ , Fe ₂ O ₃ , R ₂ O, MgO	Anorthite CaAl ₂ Si ₂ O ₈ , pyroxene, amphibole		
Al ₂ O ₃	Bauxite (raw or calcined)	40 % < Al ₂ O ₃ < 80 %; 10–15 % Fe ₂ O ₃ ; H ₂ O; SiO ₂	Gibbsite Al(OH) ₃ , diaspore α-AlO(OH), boehmite γ-AlO(OH), bayerite, corundum, goethite, hematite, kaolin, anatase	Bauxita – Bauxite – Bauxite – Bauxit	250–400€/T
	Hydrated alumina	>60 % Al ₂ O ₃ , H ₂ O, Fe ₂ O ₃ , SiO ₂	Al(OH) ₃ polymorphs		250–300€/T
	Calcined alumina	99 % Al ₂ O ₃ , Fe ₂ O ₃ , SiO ₂	Corundum		500–600€/T
	Kaoline	>45 % SiO ₂ , >35 % Al ₂ O ₃ , 13–14 % H ₂ O, Fe ₂ O ₃	Kaolinite Al ₂ Si ₂ O ₅ (OH) ₄ , quartz	Caolín – Kaolin – Caolino – Kaolin	100–300 €/T
	Pyrophyllite	>65 % SiO ₂ , >25 % Al ₂ O ₃ , H ₂ O	Pyrophyllite Al ₂ Si ₄ O ₁₀ (OH) ₂ , quartz

Prices only indicative as actual quotations strongly depend on quality (grain size distribution, iron content, and overall impurities), volumes, transportation costs (quarry-to-plant distance and transportation mode) and, of course, market-price fluctuations. RO = CaO and MgO; R₂O = Na₂O + K₂O.

Figure 1 Comparison between the compositions of the main raw materials used in glassmaking and those of some important glass products as projected in the pseudo-ternary $\text{Al}_2\text{O}_3\text{--R}_2\text{O} + \text{CaO--SiO}_2$ diagram.

Figure 2 Sieve particle size distribution (PSD) curves of the main raw materials used in glassmaking ($<40\ \mu\text{m}$ laser PSD domain). The D50 is the median diameter representing 50% of a sieved raw material. The steeper the curve, the more homogeneous is the PSD.

2.3 Operational Parameters

Another crucial feature the glassmaker has to consider for raw-material management is the mass budget. It is common knowledge that to produce 1 ton of new, cullet-free glass, one needs around 1.2 tons of raw materials. The $\sim 20\ \text{wt}\%$ mass loss is mostly due to CO_2 released by Na, Ca, and Mg carbonates. Besides free or bound water, raw materials may in addition contain other volatile components such as unbatched carbon, fluorine, chlorine,

sulfur, or boron. When present in traces, these components are not detected through standard chemical analyses (Chapter 5.1) but can nonetheless be quantified as loss on ignition (LOI) above 1000°C . It is an important specification negotiated with the raw-material supplier since the glassmaker needs it to calculate the total mass budget of the process, including the chimney emissions that are most frequently submitted to regulatory obligations.

Because the large majority of industrial glasses are oxides, they are manufactured under oxidizing conditions. The oxygen budget is a key element to control the combustion process and, thus, melting temperatures, as well as the overall color and optical transmission of the glass, which markedly depend on redox conditions ([6], Chapter 5.6). This feature is particularly important for applications such as solar panels, and is essential for glasses made with O_2 -sensitive raw materials such as coloring agents and those that contain a significant fraction of multivalent elements.

For these reasons the glassmaker must take particular care of the total chemical oxygen demand (COD) whose proper analysis is mandatory for certain raw materials entering the batch calculation. The cullet may, for instance, contain significant amounts of organic components, such as PVC, paper, or any other residues from the downstream industrial chain. Metals, besides being detrimental to the overall quality of the glass, are oxygen sinks so that they may locally shift the overall redox budget of the process when they are oxidized. For iron as a coloring agent, for example, one cannot use iron metal, whatever its grain size, but iron oxides instead. Bearing only Fe^{3+} , hematite (Fe_2O_3) is generally selected along with magnetite [Fe_3O_4] whose mixed Fe^{3+} , Fe^{2+} valence states make it suitable for reduced compositions such as amber-glass bottles. In contrast, wüstite [FeO_{1-x}] is generally of very limited use.

Finally, the apparent density is another factor needing to be specified simply because it must be known to dimension the silos where the raw materials are stockpiled at the plant site. As an example, the bulk density of quartz is 2.65 g/cm^3 . Depending on grain shapes and contact angles, that of dry quartz sand is in contrast lower than 2 as a result of a high open porosity. Practically this means that a sand-storage silo must be at least 32% bigger than estimated from the quartz density.

3 From Raw Materials to Melt

3.1 Effects of Digestion Kinetics

The sum of the oxide contents listed in Table 1 (column “bulk chemistry”) is always lower than 100 wt %. The missing few percent mainly relate to impurities. Although it would be tempting to consider them as negligible for the overall glassmaking process, these are actually significant as illustrated by building and automotive glasses, which are manufactured with the float process (Chapter 1.3). Under standard market conditions, a float line averages 600–700 tons of daily production. This pull rate requires to introduce between 500 and 600 tons of quartz sand daily into the melter. With a SiO_2 content

of 99%, about 5 tons of impurities are then introduced at the same time. Even with an expensive 99.9% quartz, there remains about half a ton of impurities. These include different minerals, highly dispersed and diluted in the bulk, some of which may simply be incompatible with the glassmaking process because refractory materials are too slowly digested by the surrounding alkali-rich molten glass.

Even quartz does not melt during the glassmaking process, but is digested at rates of a few hundred μm per hour at 1400°C [7]. It follows that 1 mm-sized quartz grain will need hours to be completely digested. That is why raw-material suppliers sieve and sort their products, and why the maximum PSD of quartz sand is fixed at less than 1 mm by glassmakers. But dissolution rates are typically as low as a few μm per hour for commonly found heavy minerals such as corundum [$\alpha\text{-Al}_2\text{O}_3$]; zircon [$ZrSiO_4$]; kyanite, sillimanite, and andalusite [the Al_2SiO_5 polymorphs]; spinel [$MgAl_2O_4$]; and chromite [$FeCr_2O_4$]. Now, corundum, for instance, melts at above 2000°C whereas the glass temperature does not exceed 1500°C at the hottest point in a melter where the average residence time of the batch is at most a few hours. As a consequence, part of the corundum introduced as mm-sized grains would survive the glassmaking process and occurs in the final product as tiny inclusions, causing mechanical stress and impairing the optical quality. Such a product would not reach the customer to be discarded instead to the internal recycling circuit or, in the worst cases, to be dumped.

The impact of such impurities may indeed be very serious. Consider a 20 m^2 , 5-mm thick float-glass slab. With a volume of about 0.1 m^3 , its weight is 200 kg and requires 170 kg of quartz sand to be made. If on average a single mm-sized grain of chromite was present in 1 kg of the sand, then the 20 m^2 slab would display 170 dot-like defects of chromite. It would clearly be unsellable since current specifications dictate that at most one dot-like defect be present in 100 m^2 of glass. To meet glassmaking specifications, raw materials thus have to be purified by the suppliers through flotation and other costly operations [4].

3.2 Quantification of Heavy Minerals

One finds approximately 150×10^6 grains of quartz in 1 kg of fine sand [4]. In such a population it is obvious that one cannot detect one grain of chromite or other impurity by routine chemical analysis. To detect these minerals at the part-per-billion (ppb) level, one rather takes advantage of the fact that they are denser, or even much denser than quartz (e.g. corundum: $\sim 4 \text{ g/cm}^3$; chromite: $\sim 5 \text{ g/cm}^3$). One can thus concentrate them by immersing the test powder in a liquid with a density slightly higher than that

of quartz, which will then float while heavier minerals will sink, allowing the harmful ones to be identified and quantified with standard methods such as optical microscopy, Raman spectroscopy, or electron microscopy [8]. For this purpose, the most frequently used liquids have long been bromoform (CHBr_3) and diiodomethane [CH_2I_2 , also called methylene iodide], whose room-temperature densities of 2.9 and 3.3 g/cm^3 , respectively, can be slightly lowered through mixing with lighter ethanol [$\text{C}_2\text{H}_6\text{O}$]. Because strict precautions must be observed to handle these toxic liquids, however, sodium polytungstate [SPT, $3\text{Na}_2\text{WO}_4 \cdot 9\text{WO}_3 \cdot \text{H}_2\text{O}$] has become an efficient alternative [9], thanks to the fact that this salt can readily dissolve in distilled water to yield liquids with a maximum density of 3.1 g/cm^3 .

Proper sampling of raw materials [4] thus is needed to guarantee their conformity with regard to possible geological heterogeneity and product variability at the quarry level. It relies on suitable quartering techniques to obtain a true fingerprint of the mineralogy of all raw materials from which incorporation of harmful species may be ruled out or at least minimized. In other words, heavy-mineral content is an overwhelming and crucial specification concerning the physical and chemical properties that must be guaranteed by a producer of raw materials, especially when fabrication of a new glass has to be tested. Not complying with these specifications can generate long-lasting yield drops and large financial losses for the glassmaker. Since glassmakers constantly need to diversify and secure their supplies of raw materials, heavy-mineral characterization must routinely be operated by well-equipped internal or academic laboratories.

Of course, the bulk chemistry must also be determined on a daily basis at the plant by XRF, ICP-MS, or wet chemistry (cf. Chapter 5.1) to monitor the variability of moisture and oxide content, especially for multielement raw materials, and thus to allow batch adjustments needed to keep the glass recipe constant to be calculated (cf. Chapter 1.3). As indicated above, the PSD, LOI, and COD parameters must in addition be included in the almost daily control of raw materials at the plant. In this way it is possible to anticipate possible drifts away from the targeted specifications of the raw-material feed. As for the overall meltability, energy demand, and expected quality, they may be tested less routinely through differential scanning calorimetry (DSC) measurements, while it should be compulsory to test the actual batch incrementally, first in the laboratory (few kg), then in a pilot furnace (~1 ton), and finally at the industrial scale (<1000 tons).

3.3 Impurity-related and Other Melting Defects

Melting quality first and foremost depends on appropriate digestion rates. *Batch stones* can, for instance, readily

occur when market requirements push glassmakers to increase pull rates and, consequently, to reduce the average residence time of the raw materials in the furnace. They also form in case of errors in batch calculation or of scale malfunction. The problem is illustrated with the overall texture and microstructure of the silica batch stone shown in Figure 3. Noteworthy are former quartz grains, whose shape have been preserved although they have been totally replaced by cristobalite (as a pseudomorph) from which newly formed tridymite lath-shaped crystals have grown radially in a groundmass of silica glass [10]. These textural features are typical of an insufficiently dispersed quartz sand within the batch.

Figure 3 Silica batch stone in a soda-lime silica glass, resulting from incomplete digestion of a lump of quartz grains as viewed under an optical microscope (a) and as observed in a thin section under transmitted light (b), where rounded grains of cristobalite formed as quartz pseudomorph are sluggishly digested while generating radially growing tridymite laths in a vitreous groundmass showing an overall open-porosity.

Regardless of the actual pull rate, the overall moisture content and distribution can provoke the formation of lumps when grains stick together at the batch plant and quickly sinter at the dog-house level, preventing natural convection within the melter from properly stirring the melt under formation. Moisture is of special concern in regions facing very wet or very cold (ice) seasons. Preheating or protecting the raw materials yard can then be an effective, but somewhat costly solution.

Quartz batch stones can also result from an inadequate overall PSD when other raw materials contain up to several weight % of free silica as impurities, whose size distribution differs from that of quartz sand. Limestone, dolomite, and feldspars are typical examples, the two carbonates having a $d_{\max}$ for quartz as high as 2 mm or more

(Figure 2). Given the aforementioned digestion rates of quartz, such large grains will end up as unmolten stones in the production process.

Refractory minerals, of course, raise special difficulties as illustrated in Figure 4 by an incompletely dissolved chromite inclusion. Its core is preserved as FeCr_2O_4 , but it is surrounded by newly formed laths of eskolaite [Cr_2O_3] radially growing from it according to the decomposition reaction:

Although Fe^{2+} then diffuses in the melt, the highly refractory eskolaite crystals (melting at 2435°C) passivate the chromite core, which will thus remain throughout the production process.

Incomplete digestion can alternatively cause the existence of vitreous inclusions called *knots* in the glassmaker jargon. The example shown in Figure 5 is that of an mm-sized pocket of alumina-rich glass within the normal soda-lime silica matrix, which represents the ghost of a feldspar crystal. As already stated, feldspar minerals melt at temperature below 1200°C , therefore early in the process, i.e. already at the dog-house level. When they do so, they generate an alumina-rich liquid phase whose viscosity of 10^5 dPa s at 1000°C is 10 times higher than that of the soda-lime silica glass [11]. At high pull rates this difference prevents rapid enough interdiffusion from taking place to ensure complete mixing between the two liquids, whence the presence of knots. A simple solution to avoid them when Al-carriers are feldspars thus is to control the PSD of these minerals. But, with very different PSD ranges, feldspars can also be present as impurities in a variety of materials such as quartz-sand, limestone, and dolomite. Likewise, a proper

Figure 4 Undissolved chromite crystal in a soda-lime silica glass as seen under a binocular microscope (a) and in a polished thin section photo under reflected light (b). The chromite grain shows a preserved FeCr_2O_4 core, exsolution lamellae, and radially growing eskolaite Cr_2O_3 laths in the outer shell.

Figure 5 A feldspar knot with about 20 wt % Al_2O_3 , enclosing bubbles (gas inclusions) in a soda-lime silica glass as seen under a binocular microscope.

PSD helps minimizing the presence of alumina-rich knots in the final product when the Al-rich phonolite and nepheline syenite rocks are used as raw materials.

Even cullet may be a source of defects, which has important practical consequences since it accounts for up to 80–90 % of the total batch for tinted soda-lime silica glasses used for packaging, and up to 30 % for standard-window and windshield glass production. In this case, the culprit is metallic aluminum from soda-drink cans that pollutes household cullet or from framework residues of window cullet coming from building demolishing sites [10]. Through the redox reaction [12]

metallic silicon forms while hydrogen is liberated by the reduction of OH-group from the glass network. The result is a sub-mm-sized silicon bead surrounded by H₂-rich gas inclusions (Figure 6), which are virtually indestructible because they are digested at rates of the order of a few μm per hour. Appropriate cullet management is thus needed to reduce this risk in glass production. For similar reasons, the absence of ceramic, porcelain, and glass-ceramic shards polluting the external cullet must also be checked carefully to avoid stones, knots, and slowing down of the production.

Another special case arises from the presence of nickel in raw materials. In sulfate-fined glasses, reduction of NiO yields nickel metal, which can react with trace amounts of sulfur to form small inclusions of NiS [mill-erite] [13]. The problem here is that this sulphide in principle undergoes near 390 °C a phase change from a high-temperature α-polymorph to a denser low-temperature β-polymorph. The kinetics are slow

Figure 6 A sub-mm-sized silicon bead surrounded by H₂-rich gas inclusions in a soda-lime silica glass, resulting from aluminum-metal contamination of recycled cullet.

enough, however, that the phase transition can take place at room temperature several days to several months or even years after tempering (Chapter 3.12). When it eventually does so, the 2–4% volume expansion generates cracking and sometimes the explosion of the finished glass product. Hence, both Ni metal and oxides are nowadays proscribed in raw-material specifications.

3.4 The Problem of Dolomite Decrepitation

Even when all chemical, physical, and mineralogical specifications are respected, some raw materials may pose special difficulties upon heating. Decrepitation is such a special case affecting mainly dolomite [14] and, albeit to a lesser extent, limestone. It occurs at 300–400 °C, hence well before the onset of decarbonation and decomposition of the (Ca, Mg) carbonate. Although it is still poorly understood [14], decrepitation appears to result from a sudden change in the overall PSD of dolomite, and an overall increase of fines, when dolomite grains locally burst into smaller grains. The decrepitation factor is defined as the increment in the fraction of grains smaller than 60 μm after heating at 1000 °C. It can range from a few to several 10% depending on geological history and, in particular, on the thermal pathway followed by the dolomite after its formation. High-decrepitation dolomites are detrimental to the glass process because they contribute to further increase in dust and carryover in the furnace atmosphere. The latter in turn contribute to clogging phenomena at the level of regenerator chambers, drastically decreasing their energy-recovery efficiency. Furthermore, dolomite dusts may increase the overall wear of the furnace-superstructure refractories through the formation of new Mg-bearing phases that decrease their overall durability. When a local supply of good-quality dolomite is lacking, glassmakers may thus find safer to produce Mg-free glass.

4 Special Raw Materials

4.1 Sodium Carbonate

Originally known as natron, sodium carbonate hydrates have been the main flux used ever since the beginnings of glassmaking. As exemplified by the celebrated Wadi el Natroun deposits in Egypt (Chapter 10.3), very pure Na₂CO₃ hydrates did form naturally but such deposits currently satisfy only about 30 % of 50 million tons used annually in industry, half of which for glassmaking. The cheapest source of sodium would be NaCl, but this salt is quite unfit for production of oxidized glasses in view of chlorinated emissions that would in particular dramatically degrade the wearing resistance of the furnace

refractories. Soda [NaOH] would be a much better alternative, but its price on an Na₂O basis is twice that of synthetic Na₂CO₃ as manufactured with the Solvay process [15], which currently supplies 59% of the market.

Sodium is most conveniently added to the batch as Na₂CO₃, whereas CaCO₃ is the most common source of carbonate ions. Hence, the goal of the Solvay process is to achieve the overall reaction:

Now, this reaction could not proceed directly in the solid state even if its Gibbs free energy of about 100 kJ/mol were not positive. But Na₂CO₃ is readily obtained through heating of NaHCO₃ precipitates at around 200 °C:

The trick of the Solvay process thus is to produce sodium bicarbonate in an aqueous solution from an NaCl brine with the reaction

which, as a by-product, yields calcium chloride, a valuable compound:

The first step then consists in producing a solution of ammonium bicarbonate with

such that NH₃ and CO₂ are in the end “totally” recycled within the process.

4.2 Raw Materials with Very Low Iron Contents

Given its strong absorption bands (Chapter 6.2), iron badly needs to be present at the lowest possible concentrations in a variety of glasses for which optical transmission must be optimized. This is, for instance, the case of the sheets protecting silicon wafers from oxidation in solar panels or of the mirrors used for concentrating solar energy in thermal solar plants. Such solar glasses are currently the most transparent available on the market with an optical transmission that can be as high as 91–92%, against values lower than 90 % for standard glasses used in windows or car windshields. Although it might appear small, this difference is in practice significant so that it is worth the subsequent increases in the cost of the raw materials. Here, two factors must be considered, namely the total iron content and the iron redox state. Whereas the latter can be controlled through various process parameters, the former is, of course, determined by the batch

composition. Specifically, the total iron content of extra-clear glasses for solar applications must be below 100 ppm [16], compared to the 600–1000 ppm of clear glass for windows. Natural raw materials with so low iron contents are rare, however, so that suppliers need beneficiation processes to reach them [4]. Grinding then becomes an issue because of potential iron contamination by the steel of the machines. Magnetic separation then is a convenient way to remove any added iron as the last step of raw-material preparation (Figure 7).

4.3 Globetrotting Raw Materials

Like other capital-intensive activities, glassmaking plants traditionally are local industries so as to minimize transportation costs of both raw materials and finished products. Although not necessarily rare geologically, however, certain minerals are not commonly found in commercially exploitable amounts with the consequence that they have to be procured globally, national policies sometimes applying heavy, protectionist custom fees to limit exportations. This situation applies, for instance, to lithium, boron, and some aluminum carriers.

In glassmaking, lithium occasionally serves as an additive (flux) for the production of standard soda-lime silica glasses, but it is mainly used for glass-ceramics to form the β -spodumene [LiAlSi₂O₆] phase that gives them very low thermal expansion coefficients (Chapter 7.11). But the price of Li₂O raw materials has been boosted – it has actually almost tripled – during the last decade, driven by the dramatically increasing demand for Li-ion batteries (Chapter 9.5). Among the available Li₂O raw materials (Table 1), Li from brines is mostly used to manufacture Li-carbonate or hydroxide (battery-grade raw materials), whereas mineral Li is incorporated into glass and ceramics. Concentrates of both minerals, spodumene and petalite, are actually crucial sources for the glass industry [17, 18], which does not require as high a purity as Li-ion battery makers. These Li-silicate sources are abundantly available in Australia, China, the United States, and Canada, but much rarer and mostly unexploited in Europe (Austria, Finland, Ireland, Portugal, and Spain) where most of the glass-ceramic industries are in fact located.

As for boron, this element is important for the production of reinforcement fibers (Chapter 1.5) and for insulation (Chapter 9.3) and textile glasses. Borates are found in Turkey, the United States, China, Russia, and South America. Turkey is the world's biggest producer and holds the largest reserves. The United States ranks second both in terms of reserves production, with about 40% of the market [19]. In this case too, the heterogeneous distribution of boron sources translates into high transportation costs as a component of the raw-material supplies.

Figure 7 Increases of iron contamination caused by grinding of quartz made with steel-bearing jaws to shift the particle size distribution. (a) Iron contents associated with the PSD curves of quartz sand and flour ground. (b) Alignment of steel particles in the magnetic field of the separator during the deferrization step of raw-material beneficiation. Picture scale of 0.5 m.

Concerning aluminum, bauxites and laterites are used as Al-carrier in standard industrial glasses. The main and largest exploited ores, representing more than 90% of the reserves, are located in Western Africa (especially Guinea), Brazil, Central America and the Caribbean (Jamaica, Trinidad and Tobago, Suriname) and Australia [20]. In this market, however, glassmakers are very distant followers of alumina-ceramics makers and especially of metallic aluminum producers whose needs are several orders of magnitude higher than theirs. In instances when relatively high contents of both aluminum and alkalis are required, it may be advantageous to use instead nepheline

syenite, a rock consisting mainly of alkali feldspars and nepheline $[\text{NaAlSiO}_4]$, which is exploited and exported from Norway, Russia (Kola Peninsula), South-Africa, Brazil, India, and China.

5 Perspectives

More than 100 million tons of glass (container, flat, fiber, and specialty) are produced yearly. In a society moving toward a CO₂-less or -free economy, extra-clear glasses

will play a key role for the development of an efficient solar energy market. As the availability of extra-pure raw materials is not infinite [16], however, beneficiation techniques will need to be improved in order to meet cost-efficient requirements adapted to the forthcoming societal challenges. In terms of both volumes and quality, middle- and long-term availability of raw materials is a major challenge for sustainable, cost-related production. But a successful low-carbon society implies the fast development of infrastructures and commodity products, which contribute to the overall industrial minerals' demand in direct competition with the glass raw materials supply chain [16]. Governmental initiatives, such as the European Union ERA-MIN Program [21] and the EIT Raw Materials, intend to build an EU-wide network linking industry, academia, and research institutes capable of sustaining the domestic supply chain of non-energy mineral resources. In parallel, efforts are made to improve batch recipes through either the use of standard raw materials with lower energy consumption [22], or totally new ways exploiting the huge potential of the recycling supply chain. Food and agriculture wastes, for instance, could allow making glass with "exotic" sources such as eggshells for Ca-carbonate, banana peels as K-carrier, or rice husk for silica [23]. Major changes are likely on the way.

1.3

Fusion of Glass

Reinhard Conradt

RWTH Aachen University, Aachen, Germany

1 Introduction

Fusion is of course the high-temperature process through which a glass is synthesized from the relevant raw materials. In this chapter, fusion and melting will be used synonymously as no preference for either term obtains in glass manufacturing. Nevertheless, the matter deserves a few comments because both are used to describe different processes under conditions of constant pressure. They may denote:

- 1) A first-order phase transition of a single-component system (such as pure H_2O , SiO_2 , or $\text{CaAl}_2\text{Si}_2\text{O}_8$) from the solid to the liquid state. This transition occurs at a unique melting (or fusion) temperature T_m where the solid and liquid coexist; between them, however, there exist discontinuities in enthalpy and entropy, which are the enthalpy (ΔH_m) and entropy ($\Delta S_m = \Delta H_m/T_m$) of melting (or of fusion).
- 2) The transition of a thermodynamically stable assemblage of different crystalline phases to the liquid state. Upon heating, such a system passes through a temperature range at which the solid and liquid phases coexist; the solidus (T_{sol}) and liquidus (T_{liq}) temperatures are the lower and upper bounds, respectively, of this interval.
- 3) The transition of any mixture of crystalline phases to the liquid state upon heating. Since such phases are not in thermodynamic equilibrium, they begin to react mutually in the solid state so that the actual path of fusion may be unpredictably complicated.
- 4) A special technique, often used by artists, to join pieces of glass together to form an object. It makes use of the fact that a glass, upon heating, undergoes gradual softening from a rigid condition below the

glass transition temperature T_g to the liquid state at $T > T_g$. At sufficiently high temperatures, glass pieces may then be joined together by viscous flow. The transition from a crystalline state is here nonexistent, which distinguishes clearly this special meaning of *fusion* from the three others.

In glassmaking, it is of course case (3) that matters, which is why it will be exclusively dealt with in this chapter. It begins with the heating of a mixture of granular solids, the *batch*, and is completed when a homogeneous liquid state is reached. Regardless of the complexity of its chemical composition, any glass is associated with a liquidus and a solidus temperature between which crystals and melt can coexist in thermodynamic equilibrium. Upon not too fast heating, a liquid for instance begins to form at the liquidus temperature of the system as determined by its overall chemical composition.

At the industrial scale, the fusion of glass is a most complex energy-intensive, high-temperature process. The transformations involved in are multiphase, multicomponent chemical reactions, which are quite different from a student's simple concept of chemical reaction. The goal of the fusion process consists in delivering a workable glass melt of high quality at high production rates and low specific-energy consumption, thereby abiding with environmental legislation. It brings together the issues of reactor technology, bulk solid melting, particle dissolution, as well as redox and acid–base chemistry of the melt. Fusion takes place in specifically designed glass furnaces. Small amounts of specialty glass are melted discontinuously in crucible, pot, or day tank furnaces; the melting compartments may be considered as crucibles of different size, ranging from a few kg to a few 100 kg. For continuous melting of small amounts of some specialty glasses, rotary kilns are used. But the vast majority of glasses is

Reviewers: E. Muijsenberg, Glass Service a.s, Vsetin, Czech Republic
C. Rüssel, Friedrich Schiller University, Jena, Germany

continuously melted in large glass furnaces whose production capacities range from a few tons to 1000 t per day.

Regardless of this diversity, fusion involves the same steps that will be successively described in this chapter. The first is the careful preparation of the batch from the appropriate raw materials. The second takes place at high temperatures through the various reactions that lead to a melt through complete dissolution of even the most refractory starting materials. The third step aims at producing a homogenous, bubble-free product by physical and chemical fining. Finally, this chapter will briefly discuss the economically and environmentally important energetics of the fusion process. A review of earlier work dealing with these issues is the feature article by Cable [1].

2 Overview of Industrial Processes

A continuously operated industrial melting process can be split into two distinct room- and high-temperature parts within which well-defined different steps may generally be identified. Their main features are as follows:

Preparation (at room temperature)

P1	Acquisition and storage of raw materials
P2	Chemical analysis of raw materials
P3	Calculation of the proportions of the batch raw materials
P4	Weighing and then mixing of the batch raw materials
P5	Intermediate storage of the batch in a buffer silo
P6	Batch charging

Glass melting (at high temperatures)

M1	Primary batch-to-melt conversion, yielding a <i>rough melt</i> still containing considerable amounts of gas bubbles and undissolved solids Time demand: about one hour Intrinsic energy demand: about 2000 MJ/t of produced glass (3.6 GJ = 1 kWh) Temperature range: 600–1200 °C
M2	Sand dissolution (comprising the dissolution of any other crystalline solids) Temperature range: 1200–1400 °C Intrinsic energy demand (mostly for heating up the melt): approx. 280 MJ/t of glass
M3	Fining, i.e. physical removal of residual bubbles via the thermochemical generation of an adequately high-volume fraction of large bubbles of a fining gas Temperature range: 1400–1500 °C Intrinsic energy demand (for heating-up): approx. 140 MJ

M4	Refining, thermal, and chemical homogenization, whereby refining denotes the resorption of residual gas bubbles upon steady cooling Target temperature: 1350 °C Heat released: –220 MJ.
----	---

At the end of step M4, the melt is finally conveyed to the forming area where it is transformed into hollow ware (Chapter 1.5), or flat glass (Chapter 1.4), or any other type of product. To maintain a high glass quality, the filling level of the melting compartment must be kept constant. Therefore, the sequence of process steps P1 to M4 must be well balanced logistically. This constraint puts a stringent time interval to act for online corrections to steps P4–P6; the buffer silo between steps P5 and P6 thus serves the sole purpose of widening this interval. Along the path from P6 to M4, no action for correction is possible at all.

3 Batch Preparation

3.1 Raw Materials

The fusion of a glass of a given composition requires a suitable set of raw materials (Chapter 1.2). These are selected according to their availability and quality, which, in turn, determine their price. The issue of availability may be complex since it includes geological occurrence (for natural materials), production capacity (for manufactured materials), infrastructure for recycling and upgrading (for cullet) as well as transport distance, number of tenders, political stability at the source, etc. Quality is likewise a manifold issue as it concerns chemical composition (from impurities to the main component), mineralogical composition (special attention being paid to side minerals difficult to melt), and grain size distribution (with a particular concern to under- and oversized grain fractions). Among chemical impurities, iron is a critical factor. It is present in virtually every natural raw material but is generally tolerated in glass only at very low levels (Table 1) except, of course, when it is itself a major component of the product as in fire-resistant glass fibers (Chapter 9.3). Here, the iron content is given in terms of stoichiometric Fe_2O_3 irrespective of its actual valence state. Yet, iron is generally present as Fe^{2+} and Fe^{3+} whose relative abundances depend on the redox state of the melt. Owing to the strong absorption bands of both cations, iron has a strong impact on the color of the glass even at low concentrations (Chapter 6.2). And because of its strong absorption in the 600–4000 μm wavelength range, which is that of the heat radiation in the furnace, Fe^{2+} acts as a blinding agent to limit tightly the

Table 1 Maximum iron contents in various types of glasses, given in ppm of stoichiometric ferric iron (Fe_2O_3).

Glass type	ppm Fe_2O_3
Optical glass	10
Ultra-white glass	100
Continuous fibers	200
Flint container glass	250
Standard float glass	300
Amber container glass	2 500
Cr-green container glass	10 000

**Figure 1** Absorption bands of Fe^{2+} , Fe^{3+} , and Cr^{3+} in a glass melt, and radiation intensity in the combustion space of a furnace illustrated in a simplified way by black-body radiation emitted at 1600°C from the upper lining (the crown) of the furnace; relative intensities.

transparency of the melt to IR radiation (Figure 1). In Figure 1, the furnace radiation is illustrated by a black-body-type curve. This is an oversimplification. The actual flame radiation spectrum in a furnace is characterized by strong emission lines of the H_2O and CO_2 molecules in the flame (H_2O : $0.9\text{--}1.1$, $1.8\text{--}2.0$, $2.5\text{--}3.2\ \mu\text{m}$; CO_2 : $2.7\text{--}3.0$, $4.2\text{--}4.7\ \mu\text{m}$) and by black-body radiation from soot particles. The radiation enters the melt directly to a certain extent; however, chiefly via emission (emission coefficient $\varepsilon \approx 0.5$) and diffuse reflection from the top lining (the crown) of the furnace. The curve shown in Figure 1 is an envelope of the actual radiation only. Irrespective of the above details, furnaces in which glasses with high Fe^{2+} contents are melted thus exhibit large vertical temperature gradients and low bottom temperatures; heat transfer from the combustion space has then to be brought about by the convective motion of

the melt. By contrast, melts with very low amounts of Fe^{2+} weakly absorb energy from the combustion space since Fe^{3+} does not influence IR absorption. As a consequence, they display high temperatures at the bottom of furnaces. Controlling the redox state of the melt thus is important not only for color generation but also for furnace operation, a general conclusion that also applies for instance to green glasses colored by Cr^{3+} .

3.2 Calculation of Batch Composition

An accurate chemical analysis of every raw material is a prerequisite for batch preparation (Chapter 1.2). On this basis, one swiftly determines the batch composition by solving a system of linear equations where data are arranged in a specific way (Table 2). First, the total number of different oxides in the raw material basis is determined (6 in the example shown). The target glass composition is entered as an oxide column vector Y_{TARGET} . The large matrix shaded in gray contains the results of raw-material analyses. It is arranged in the order of carriers of the respective glass oxides. For each oxide that is not represented by a specific raw material, the entry 1 is filled in the matrix. If an oxide has more than one carrier raw material (in the example, Al_2O_3 has two carriers, namely feldspar and Calumite®), then their ratio has to be specified, and the respective column entries are merged to a single column in proportion of this ratio. Through these operations, the gray area takes the form of a square matrix M . Next, a preliminary vector R_{PRE} of the batch composition is obtained from the product $R_{\text{PRE}} = M^{-1} \cdot Y_{\text{TARGET}}$. It may contain negative figures since it is impossible to make for example an iron-free glass from iron-containing raw materials. To derive the actual batch-composition vector R , these negative figures are thus set to zero. The real glass composition is then given by the product $Y_{\text{REAL}} = M \cdot R$ before Y_{REAL} is normalized to 100 wt % and R to 1000 kg of resulting glass, or 2000 kg of sand (see following paragraph), or to any other convenient reference mass.

Final adjustment of the batch composition still requires allotments of the appropriate agents for controlling glass color, fining (as described in Section 5.2), redox conditions, and, thus, valence states and oxygen complex formation of polyvalent ions (cf. Chapter 5.6) at the industrial scale. For adjustment of the redox state, the so-called redox number concept [2] is widely accepted and empirically applied in industry. This incremental system assigns a specific redox factor R_i to every member of a set of redox-active ingredients i (Table 3). In the example of Table 4, the batch composition from Table 2 is complemented by 4 kg of sulphate (the amount of soda ash being reduced accordingly to maintain an identical amount of Na_2O in the glass). Then the batch

Table 2 Batch calculation scheme.

Salt cake; sulfate	Na ₂ SO ₄	+0.67
Gypsum anhydrite	CaSO ₄	+0.70
Sodium dichromate	Na ₂ Cr ₂ O ₇	+0.77
Manganese oxide	MnO ₂	+1.09

composition is normalized to amounts $m_{III}(i)$ per 2000 kg of sand, and the total redox number of the batch is calculated from the weighted sum $R = \sum R_i \cdot m_{III}(i)$. It is true that this number R does not have a straightforward scientific meaning but it allows one to set in a well-defined way the redox state to a desired level. For redox numbers in the

interval $-25 < R < 25$, a fair estimate of the Fe^{2+}/Fe_{total} ratio for is given by $0.4 - 0.015 \cdot R$. Because the chemical composition of the batch can no longer be corrected after charging, these rather simple calculations are mandatory for any successful melting process.

Finally, the raw materials are automatically weighed in proportions determined by batch calculations, conveyed to a mixer, and thoroughly mixed. During mixing, typically 2–3% of water is added to suppress dust formation and segregation induced either originally by transportation or subsequently by mixing. In batches containing soda ash, small amounts of this product dissolve in the water before reprecipitating on other batch grains. This process termed “impregnation” actually enhances the kinetics of batch melting.

4 The Conversion of Batch into Melt

4.1 The Basic Importance of Convection

In principle, the melting compartment (the *tank*) is a shallow basin whose typical dimensions (length $L \times$ width $W \times$ depth D) are $10 \times 6 \times 1 \text{ m}^3$ for medium-size container-glass furnaces and $30 \times 10 \times 1.4 \text{ m}^3$ for float-glass furnaces. The required energy is delivered in a combustion space right above the melting compartment and transferred to the melt chiefly by black-body radiation. Additional energy (5–20%) is delivered by direct electrical heating (*boosting*) of the melt.

The very melting process, i.e. steps M1–M3, takes place in one single box-shaped compartment as sketched in Figure 2a, b. The sketches illustrate some essential

Table 4 Scheme for final batch adjustment with sodium sulphate set to 4 kg/t glass for a targeted redox number R of -24.

Raw material i	$m_i(i)^a$	$m_{II}(i)^b$	$m_{III}(i)^c$	$R(i)$	$R(i) \cdot m_{III}(i)$
	kg/t glass	kg/t glass	kg/2000 kg sand		
Sand	674.28	674.28	2000.00		
Feldspar	44.02	44.02	130.57

Figure 2 Convection cells (vortices) in the melting tank of a glass furnace (vertical projection): (a) float glass furnace (side port firing), transit to the refining zone indicated by the dotted vertical line on the right-hand side; (b) end port fired container glass furnace, transit to the refiner through a narrow opening at the lower right (the “throat”); D = depth of the tank.

features only (see Chapter 9.7 for details). Spatially, the individual process steps are separated – not in a rigorous but effective way – by two convective vortices. In furnaces with transversal flame direction (so-called side port fired furnaces; flow pattern Figure 2a), these are mainly generated thermally by an appropriate distribution of fuel input to a series of burners arranged along the L axis above the melt. This results in two well-developed vortices with a well-localized hot spot at the position of maximum energy input. In furnaces with longitudinal flame direction (end port fired furnaces; flow pattern Figure 2b), the energy input via combustion along the L axis cannot be controlled at the same distinction as in a side port fired furnace. Here, the flow pattern is typically dominated by a single predominant vortex; the hot spot is shifted toward the end of the furnace. Local stabilization of the vortices is achieved by electrical heating from below, and – for the second type of furnaces – also mechanically by the action of air bubblers or by implementation of a solid barrier (a *wall*) at the bottom of the tank. As seen from Figure 2, the batch floats on the surface of the molten phase and melts continuously in the L direction, thereby typically covering an area whose length is about $L/3$, or more than $2L/3$ for side and end port firing, respectively. Processes M2 (sand dissolution) and M3 (fining) then take place in the first and second vortices, respectively. Note that the first vortex conveys very hot melt right underneath the batch, helping to satisfy the very high intrinsic energy demand of melting. As for the second, it transports a very hot (hence low-viscosity) melt along the surface area, thereby facilitating the escape of rising bubbles. This effect is especially pronounced in the pattern shown in

Figure 2a while in Figure 2b, a large portion of the melt does not reach the surface at all.

At a given pull rate p in t/h, the nominal overall dwell time of the melt in the furnace is

$$\tau_{\text{NOM}} = \rho L W D / p \quad (1)$$

where ρ is the density of the melt and $L \cdot W \cdot D$ the volume of the melting tank. Depending on the size of the furnace and the targeted glass quality (in terms of residual bubbles), τ_{NOM} ranges from 20 to 40 hours. During this time, the average volume element circles 2–6 times in vortex 1, and about twice in vortex 2. For a detailed analysis of the role of the flow pattern on melting and fining, see [3, 4]. The process of refining (M4) already starts at the descent of vortex 2; it is completed in a subsequent compartment termed *refiner*, which is thermally separated from the *melter*. Thermal separation is accomplished either with a vertical wall leaving an opening of about $0.5 \times 0.3 \text{ m}^2$ cross section (the *throat*) at half width right above the bottom of container-glass furnaces (Chapter 1.5), or by an area of moderately narrowed width (the *waist*) in float glass furnaces (Chapter 1.4). For the sake of glass quality (i.e. homogeneity), it is mandatory to keep the position of the hot spot constant at any pull rate.

4.2 The Chemistry of Melting

The first high-temperature process is primary melting of the batch. It is typically accomplished within one hour and is characterized by a very high energy demand and

the release of CO_2 from the carbonated raw materials. For a glass batch, the individual reactions involved are the following ones:

- 1) *Physical melting of salt-like raw materials*, Na_2CO_3 , Na_2SO_4 , NaNO_3 , NaOH , NaCl , etc.
- 2) *Evaporation of batch and hydrate water* in the temperature range $100\text{--}600^\circ\text{C}$.
- 3) *Decomposition of limestone and dolomite*:

- 4) *Formation of a double carbonate*: $\text{Na}_2\text{CO}_3 + \text{CaCO}_3 \rightarrow \text{Na}_2\text{Ca}(\text{CO}_3)_2$ near 785°C ; in conventional batches, this is a side reaction of only minor importance.
- 5) *Formation of silicate melts*. These reactions assume noticeable turnover rates only after actual melting of soda ash:

Formation of ternary melts (eutectic $\text{NS--NS}_2\text{--N}_2\text{CS}_3$: 821°C , eutectic

- 6) *Sulphate coal reaction*: $\text{Na}_2\text{SO}_4 + 4\text{CO} \rightarrow \text{Na}_2\text{S} + 4\text{CO}_2$ at approx. 900°C .

- 7) *Reactions with cullet*. Although it appears as a neutral post in the energy balance, cullet vigorously react with soda ash; very fine cullet compete with sand for soda ash, delaying sand dissolution.

The liquidus temperatures and viscosities of the primary melts forming during the early stages of batch melting are plotted in Figure 3 in the cases of binary salt-like melts formed from soda ash and another compound (Figure 3a) and of the systems $\text{Na}_2\text{O--SiO}_2$, $\text{Na}_2\text{B}_4\text{O}_7\text{--SiO}_2$, and $\text{B}_2\text{O}_3\text{--SiO}_2$ (Figure 3b).

Owing to their extremely low viscosities, the salt-like primary melts play an important role in bringing about high turnover rates during batch melting. When they are lacking, as in alkali and boron-free continuous fiber glasses, the products in contrast remain in a granular state until they reach their lowest eutectic temperature (compare with Figure 6b in Chapter 6.1).

These different stages of early batch melting are sketched in Figure 4 for a soda lime silicate glass batch. Before a soda-ash melt forms, the batch remains in a granular state (Figure 4a). Then, a primary salt-like, low-viscosity melt rapidly spreads throughout the batch, thereby wetting the solid grains (Figure 4b). This stage is characterized by a large ratio between the liquid interface and the melt volume. It is predominantly at this time that diffusion paths for oxygen exchange are short and that the surrounding atmosphere effectively interacts with the melt to determine its final redox state.

Upon further melting (Figure 4c, d), the melt becomes increasingly viscous and the ratio of liquid interface to melt volume decreases. In a real batch heap, stages (a) to (d) proceed longitudinally along the L axis (see Figure 2) and vertically from the outside to the inside of the batch. The batch melts from both its top and

Figure 3 Liquidus temperatures and viscosities (dPa·s) of primary melts formed during the early stages of batch melting. (a) Binary salt-like melts formed from soda ash and another compound. (b) Primary oxide melts in the systems $\text{Na}_2\text{O--SiO}_2$, $\text{Na}_2\text{B}_4\text{O}_7\text{--SiO}_2$, and $\text{B}_2\text{O}_3\text{--SiO}_2$. Invariant points indicated by open circles.

Figure 4 Early stages of batch melting, manually sketched after the scanning electron microscopy micrograph. (a) Open-pore stage with granular solids and gas, the gas composition being dominated by the equilibrium between CO_2 and O_2 from trapped air and the furnace atmosphere. (b) Closed-pore stage with the development of a widespread primary liquid, a large ratio s of effective liquid interface (solid/liquid and solid/gas) and liquid volume, and a gas composition dominated by CO_2 , redox active materials, and polyvalent ions in the primary melt. (c) Reaction-foam stage characterized by large volumes of granular solids, bubbles, and melt, and by progressive melting of solids and decreasing s ratios. (d) Rough-melt stage, the melt being the predominant phase coexisting with considerable amounts of bubbles and undissolved grains and showing on top a seam of the primary foam formed.

bottom side, typically in an almost symmetrical way as the heat fluxes from above and below are of the same order of magnitude. The release of gases is in contrast asymmetric since those from the upper parts readily escape whereas those coming from the lower parts remain trapped below the batch. In a successful primary melting process, the majority of solids are digested, only a minor part being released to the rough melt. This requires good batch mixing and a well-balanced granulometry of the raw materials. The issue can be tested at the lab scale by so-called batch-free time crucible tests. In these simple tests, batch samples of 50–100 g are exposed to a laboratory furnace at 1400°C and the progress of melting is inspected visually after a given time.

4.3 Sand Dissolution

All solids surviving primary batch melting have to dissolve in the viscous rough melt by slow diffusion processes under comparatively low driving chemical forces. This is one of the reasons why, even today, long dwell times are required for the fusion process. By mass, the sand represents the major part of solids that have to dissolve in this way. The process suffers from an especially unfavorable feature (Figure 5): the decrease of the silica concentration from the sand grain to the melt phase represents a strong chemical gradient that causes the grain to be surrounded by a seam of melt with a high viscosity and a low basicity. This gradient affects not only

Figure 5 Schematic view of a dissolving sand grain; the grain is surrounded by a solid reaction layer (e.g. tridymite) followed by a liquid high-viscosity diffusion seam with decreasing SiO_2 concentration, hence decreasing acidity, from inside to outside; gas bubbles – mostly O_2 – precipitate at the interface solid/liquid; upon complete dissolution of the sand grain, a bubble cluster remains in the melt.

mass transport but also the solubility of gases, which generally decreases with decreasing basicity (cf. Chapter 5.7). Thus, gases dissolved in the rough melt tend to form bubbles around a dissolving sand grain.

In addition, temperature-induced reduction of ferric iron takes place as described by the reaction

describing how firm $[\text{Fe}^{3+}\text{O}_4]$ oxygen complexes give rise to the weak $[\text{Fe}^{2+}\text{O}_6]$ complexes formed by ferrous iron. The equilibrium constant of the reaction is given by

$$K_p = \frac{[\text{Fe}^{2+}]}{[\text{Fe}^{3+}]} \cdot [\text{O}^{2-}]^{7/2} \cdot P(\text{O}_2)^{1/2} \quad (3)$$

so that, at constant redox state, tiny oxygen bubbles emerge at the boundary of the dissolving grain. Any dissolving sand grain leaves behind it a cluster of small bubbles, removal of these bubbles makes sense only if their generation is over. This is one of the reasons why sand dissolution and the fining process need to take place in separate parts of the furnace.

In summary, successful sand dissolution is a prerequisite for successful fining. Even apparently small differences in the grain-size distributions of sands have a big impact in this respect. This statement will be demonstrated for two different sands. Let us assume that a spherical sand grain with radius r dissolves according to Jander's kinetics:

$$\alpha(r, t) = 1 - \left(1 - \sqrt{\frac{t}{t^*(r)}}\right)^3, \quad t^*(r) = \frac{r^2}{4 \cdot D}. \quad (4)$$

Figure 6 Grain-size distributions of two different glass-grade sand qualities as determined with sieves of increasing mesh width.

Here, $\alpha(r, t)$ denotes the turnover, with $0 \leq \alpha(r, t) \leq 1$ and D a diffusion coefficient. The grain-size distribution is mathematically represented by a log-normal distribution, the differential form of which reads

$$q(r) = \frac{1}{\sqrt{2\pi} \cdot \sigma \cdot r} \cdot \exp \left[- \left(\frac{1}{\sqrt{2} \cdot \sigma} \cdot \ln \frac{r}{r_{50}} \right)^2 \right], \quad (5)$$

where r_{50} is the median radius of the particle size distribution and $\sigma = \frac{1}{2} \cdot \ln(r_{84}/r_{16})$ is the standard deviation denoting the width of the distribution; 16 and 84% by mass of the sand are contained in the fraction smaller than r_{16} and r_{84} , respectively. The values of r_{50} and σ are determined by an evaluation of the sieve analysis (Figure 6). Both sand qualities have an identical median $d_{50} = 2 \cdot r_{50} = 180 \mu\text{m}$, but different σ . An ensemble of grains with a size distribution $q(r)$ then dissolves according to the equation

$$A(t) = \int_0^{r=\sqrt{4Dt}} q(r) dr + \int_{r=\sqrt{4Dt}}^{\infty} \alpha(r, t) q(r) dr \quad (6)$$

where $0 \leq A(t) \leq 1$ denotes the reaction turnover of the entire ensemble. The results for the two selected sand qualities upon isothermal dissolution are shown in Figure 7 as obtained with the solution of Eq. (18) given in the Appendix. At first sight, both kinds of sands dissolve in about the same manner. But on closer

Figure 7 Dissolution turnover of the two sands of Figure 6 as a function of process time for isothermal diffusion with $D = 1 \cdot 10^{-13} \text{ m}^2/\text{s}$. Inset: magnification of the results for nearly complete dissolution.

inspection (see inset), the difference does become large toward the very end of the process since Sand 2 needs significantly many more hours than Sand 1 to reach a 99.9% dissolution level, which is crucial for glass quality.

5 Fining, Refining, Homogenization

5.1 Physical Fining

As noted above, the ideal onset of fining takes place when sand dissolution is complete. Physically, fining relies on two simultaneous processes, namely bubble removal by buoyancy and coalescence of small bubbles to form larger ones. The latter is driven by the release of energy associated with the excess internal pressure of a bubble relative to ambient. As given by Laplace's formula, this excess pressure is $\Delta P = 2\sigma/r$ for a bubble of radius r with a surface tension σ so that the energy gained amounts to about $3.5 \cdot \sigma \cdot r$ when two bubbles of identical size merge. As for the buoyancy velocity v_0 of a single bubble in a melt of viscosity η , it is given by a modification of Stokes' law for dispersed phases with mobile boundaries known as Hadamard's law:

$$v_0 = \Delta \rho g r^2 / 3\eta, \quad (7)$$

where g is the gravitation constant and $\Delta \rho$ the density difference between the melt and bubble.

For a melt with a volume fraction ϕ of bubbles, the effective viscosity becomes

Figure 8 Rising velocity v_{SLIP} of bubble swarms in a melt at a viscosity of 150 dPa·s as a function of bubble radius r and volume fraction ϕ of bubbles.

$$\eta_{\text{eff}} = \eta (1 - \phi / \phi_{\text{max}}) \quad (8)$$

where $\phi_{\text{max}} = 0.64$ is the maximum value of ϕ as given by random close spherical packing. But the density decrease caused by the presence of bubbles, which is proportional to $1 - \phi / \phi_{\text{max}}$, must also be taken into account. The rising velocity v_{SLIP} of an individual bubble within a bubble swarm of volume fraction ϕ thus is

$$v_{\text{SLIP}} = v_0 \eta / \eta_{\text{eff}} = \Delta \rho g r^2 / 3\eta (1 - \phi / \phi_{\text{max}})^2. \quad (9)$$

The situation is illustrated in Figure 8 for a viscosity of 150 dPa·s, which is that of a typical float glass melt near 1400 °C. Up to a volume fraction of 0.4, bubbles bigger than 0.5 mm in radius safely escape during the available process time, whereas those smaller than 0.1 mm hardly reach any noticeable rising velocity. They rather rest relative to the environment. An especially critical situation occurs when the volume fraction approaches the limit ϕ_{max} . In this case, bubbles of any size become stagnant so that a foam forms on top of the melt in the fining area as observed in a glass of beer. Hence, this problem calls for utmost care in the design of the chemical part of the fining process, and especially of the amount of fining agent used.

5.2 Chemical Fining

As indicated by old glass specimens, bubbles cannot be completely eliminated with only physical fining. In a somewhat paradoxical way, better results are achieved if additional bubbles are produced within the melt at a sufficiently high, yet not too high, volume fraction to coalesce with the bubbles formed or entrapped during

melting. The process is known as *chemical fining* as it involves reactions with gas-releasing substances.

For reasons of cost, chemical compatibility, and effectiveness, the most widely used agent is sodium sulphate (Na_2SO_4). By experience, 4 kg of Na_2SO_4 are added per ton of produced glass. During the early stages of batch melting, the sulfate dissolves in the melt. Under oxidizing conditions, it decomposes at 1400–1450 °C according to the reaction

where the braces $\{-\}$ denote the state “dissolved in the melt.” Under reducing conditions, sodium sulphate reacts with the Na_2S formed during primary batch melting as follows:

The latter reaction already occurs at temperatures slightly below 1400 °C.

Oxygen fining is an alternative option. The agent typically used is Sb_2O_3 ; it is added to the batch in amounts of 3–5 kg per 1000 kg of sand, in combination with a four- to eightfold amount of NaNO_3 [5]. At the moderately low temperatures of primary batch melting, Sb_2O_3 converts to $\{\text{Sb}_2\text{O}_5\}$ provided that a sufficiently high oxygen partial pressure in the batch is established (Figure 4, stage b). This is achieved by the action of NaNO_3 , which decomposes at batch melting temperatures to release oxygen:

At increasing temperatures, the higher valences of polyvalent ions become increasingly unstable (see Chapter 5.6) so that the fining reaction actually reads

The release of oxygen bubbles reaches its maximum at about 1300 °C and extends beyond 1400 °C. The negative side effect of this procedure is the formation of the NO_x pollutant.

A simple calculation will finally explain why experience and empirical knowledge still play the predominant role in the allotment of fining agents. As used in the batch in Table 4, a mass of 4 kg of Na_2SO_4 represents 56.3 mol of SO_2 , which, at 1400 °C, 1 bar, would fill a volume of 7.6 m³. Now, 1 ton of melt, by contrast, fills 0.4 m³ only. Obviously, only a very minor part of the nominal SO_2 ends up in gas bubbles otherwise a foam instead of a clear melt would be obtained. The major part of SO_2 is in fact lost during batch melting, by evaporation from the melt surface, or is retained in the glass. Thus, the proper

allotment of fining rests on the small difference between sulfate input and the above losses. One of the rare attempts to perform a detailed sulfur balance of a glass furnace revealed that approximately 0.25–0.3 kg of the sulfate added per t of glass are released in the form of fining bubbles [6].

5.3 Homogeneization

After the fining process, the melt is cooled down and homogenized thermally in a steady way. Small residual bubbles resorb themselves because the solubilities of most volatile species strongly decrease with increasing temperatures (Chapter 5.5). For this reason, care has to be taken to prevent local temperature rises from happening during the homogenization process otherwise the so-called *reboil bubbles* would form in the melt and could not be removed in any way. Among dissolved gases, N_2 distinguishes itself by its decreasing solubility with decreasing temperatures. Thus, N_2 -containing bubbles escaping the fining process appear as very tiny bubbles called *seeds* in the final glass. Their number per unit mass of glass represents an important quality criterion. In container glass, a few tens of seeds per 100 g of glass are accepted. Float glass requires a much higher quality (one visible defect per 20 m² already is considered a high defect density) and hence, much longer dwell times (approx. 1.5–2 days vs. 1 day for container glass) in the melting compartment.

6 Energetics of Glass Melting

The amount of energy involved in the fusion of glass is an issue of great interest to the glass industry. Referring to comprehensive quantitative treatments ([7, 8] and Chapter 9.8), we will give only a brief sketch of this issue within the scope of this chapter. The approach rests on the fact that, at constant pressure, the heat (enthalpy) transferred to or drawn from a system is thermodynamically the variation of a state function: as such, the intrinsic energy demand depends only on the initial and final states of the system and it can be determined without any consideration of what is going on along the process road.

The initial enthalpy state is given by the sum of standard enthalpies H°_i at 25 °C, 1 bar, of the individual raw materials i , weighted by their respective amounts m_i in the batch:

$$H^\circ_{\text{BATCH}} = \sum m_i \cdot H^\circ_i. \quad (14)$$

The final enthalpy is given by the standard enthalpies of the batch gases g , $H^\circ_{\text{GASES}} = \sum m_g \cdot H^\circ_g$, and of the glass,

H°_{GLASS} , plus the heat content $\Delta H(T_{\text{ex}})$ of the glass at the exit temperature T_{ex} . The standard enthalpy difference between inputs and products constitutes the chemical energy demand

$$\Delta H^\circ_{\text{chem}} = H^\circ_{\text{BATCH}} - H^\circ_{\text{GASES}} - H^\circ_{\text{GLASS}}. \quad (15)$$

The heat content of the melt at T_{ex} is given by $\Delta H(T_{\text{ex}})$. For convenience, all enthalpy values are inserted in absolute figures, disregarding the minus sign given in thermochemical tables. The overall intrinsic heat demand H_{ex} (exploited heat of the process) is given by

$$H_{\text{ex}} = (1 - y_{\text{CULLET}}) \cdot \Delta H^\circ_{\text{chem}} + \Delta H(T_{\text{ex}}), \quad (16)$$

where y_{CULLET} denotes the weight fraction of cullet per amount of glass produced.

It is true, real raw materials typically do not contain their main mineral phase only, but also contain minor amounts of side minerals. For example, a real quartz sand may contain, beside its main phase quartz, minor amounts of feldspar minerals, magnetite, spinel, etc.; a natural dolomite is typically composed of different minerals forming solid solutions in the system Ca–Mg–Fe^{II}–CO₃ with an overall composition not too far from the pure phase CaMg(CO₃)₂. An accurate determination of the enthalpy values H°_i of real raw materials would thus require the evaluation of multicomponent phase diagrams. However, such an approach would hardly be accepted by the technological community. Beyond this, the gain of accuracy against a simpler approach is minor only. Thus, with the reservation to a more rigorous treatment [7, 8], only the enthalpy values H°_i of pure raw materials are given here in units of MJ/kg:

Raw material <i>i</i>	Enthalpy H°_i in MJ/kg
Pure quartz sand	15.150
Pure albite (NaAlSi ₃ O ₈)	14.952
Pure dolomite CaMg(CO ₃) ₂	12.549
Pure calcite CaCO ₃	12.058
Soda ash	10.659
Sodium sulfate	9.782
Carbon	0.000
Calumite®	13.561

For the batch gases, the following values hold:

CO₂: 8.941; H₂O: 13.422; SO₂: 4.633; O₂: 0.000.

The energy calculation for the real glass composition of Table 2 (where the tiny amount of TiO₂ has been allotted to SiO₂) is summarized in Table 5. The position of the

glass composition in the phase diagram in units of kg of equilibrium compounds per t of glass is found by the following simplified procedure:

$$\begin{aligned} \text{NAS}_6 &= 51.440 \text{ Al}_2\text{O}_3 - 55.697 \text{ K}_2\text{O}, \\ \text{KAS}_6 &= 59.102 \text{ K}_2\text{O}, \\ \text{hm} &= 6 \text{ Fe}_2\text{O}_3, \\ \text{FS} &= 7.345 \text{ Fe}_2\text{O}_3, \\ \text{MS} &= 24.907 \text{ MgO}, \\ \text{NC}_3\text{S}_6 &= 35.112 \text{ CaO}, \\ \text{NS}_2 &= 29.386 \text{ Na}_2\text{O} + 19.346 \text{ K}_2\text{O} - 17.867 \text{ Al}_2\text{O}_3 \\ &- 10.824 \text{ CaO}, \\ \text{S} &= \text{difference to 1000 kg}. \end{aligned}$$

Oxide amounts are to be inserted in wt %. For the components *k*, the shorthand notation hm = FeO·Fe₂O₃, F = Fe₂O₃, M = MgO, C = CaO, N = Na₂O, K = K₂O, S = SiO₂ is used. Column m(*k*) in Table 5 lists the resulting amounts of the constitutional components of the glass. By this procedure, one finds that the standard enthalpies of formation of the glass and melt are 14 189.7 MJ/t at room temperature and 12 665.9 MJ/t at 1300 °C, respectively. The enthalpy physically stored in the melt at 1300 °C relative to the glass at 25 °C is thus 1523.8 MJ/t. By the weighted sum of the heat capacity of compounds *k*, the latter value can be adjusted to any other exit temperature of the melt. For the batch given in Table 4, column “*m_{II}(i)*”, a chemical energy demand of $\Delta H^\circ_{\text{chem}} = 461.8$ MJ/t is obtained. Fusion of the selected batch with 50% cullet ($y_{\text{CULLET}} = 0.5$) thus requires an intrinsic energy demand of

$$\begin{aligned} H_{\text{ex}} &= (1 - y_{\text{CULLET}}) \cdot \Delta H^\circ_{\text{chem}} + \Delta H(T_{\text{ex}}) \\ &= 1745.7 \text{ MJ/t}. \end{aligned} \quad (17)$$

A well-constructed and operated melting furnace (end port, air-gas fired) reaches an efficiency of heat exploitation η_{ex} of 48%. Thus, the actual energy demand H_{in} of the melting process amounts to $H_{\text{in}} = H_{\text{ex}}/\eta_{\text{ex}} = 3637$ MJ/t. This result is very much in line with industrial experience. Calculations of this kind are of high importance for the evaluation of glass furnace performance [9], for furnace design, as well as for the energy optimization of batch and glass compositions.

7 Perspectives

Although the energetics of the fusion process may be considered as satisfactorily assessed, the kinetic aspects of fusion are not yet well enough understood. The efficiency of heat exploitation η_{ex} of a furnace varies according to a hyperbolic law of the type $\eta_{\text{ex}} = 1/(A + B \cdot p)$ with the production rate *p* (t/h). Thus, furnaces are preferentially operated at the highest achievable rates. The limits for *p* are determined by the rate of heat transfer or the time

^a $H^\circ_{k, \text{GL}}$ = standard enthalpy of component *k* in the glassy state; $H_{k, 1300}$ = enthalpy of *k* in the liquid state at 1300 °C; $c_{p, k, L}$ = isobaric heat capacity of liquid *k*; $m(k)$ = equilibrium amount of *k* in the multicomponent phase diagram; H°_{GLASS} = standard enthalpy of the resulting glass;

$H_{1300, \text{MELT}}$ = enthalpy of the melt at 1300 °C; ΔH_{1300} = heat content of the melt at 1300 °C relative to the glass at 25 °C.

^b hm = FeO·Fe₂O₃, F = Fe₂O₃, M = MgO, C = CaO, N = Na₂O, K = K₂O, S = SiO₂.

demand of the fusion process required to achieve an acceptable glass quality. As of now, however, one does not even know which of the above constraints controls the melting rate. As a matter of fact, the answer depends on both furnace and batch design.

A better understanding of redox and acid base reactions in real furnaces is also desired. Although these reactions are well understood at the laboratory scale, the transfer to a real production situation is still set by experience rather than by scientific principles. In view of the large impact of these reactions on glass quality, progress in this area would be highly appreciated.

Finally, the glass industry is engaged in a quest to lower its overall energy consumption to decrease its operating costs and to satisfy increasingly stringent legislation imposed on high-temperature industrial processes. The design of faster conversion batches is becoming important in this respect. Conventional glass formulae and batch recipes are no longer taken for granted. Efforts are in particular made to design batches that would melt along reaction pathways ensuring higher turnover rates than current randomly mixed batches. Progress may be achieved with selective batching, granulation processes bringing the reaction partners into close contact at the μm scale, preparation of core-shell type pellets, or selective preheating of specific raw-material combinations of the batch. In each case, of course, a prerequisite would be that the obtained energy savings are not offset by increased batch costs.

Appendix

The results plotted in Figure 7 for the dissolution of an ensemble of grains have been obtained from the analytical solution to the integral $A(t)$ of Eq. (6) given by:

$$\begin{aligned}
 A(t) = 1 - \frac{1}{2} \cdot \operatorname{erfc}\left(\frac{1}{s} \cdot \ln y\right) + \frac{3y}{2} \cdot \exp\left(\frac{s^2}{4}\right) \cdot \operatorname{erfc}\left(\frac{1}{s} \cdot \ln y + \frac{s}{2}\right) \\
 - \frac{3y^2}{2} \cdot \exp(s^2) \cdot \operatorname{erfc}\left(\frac{1}{s} \cdot \ln y + s\right) \\
 + \frac{y^3}{2} \cdot \exp\left(\frac{9s^2}{4}\right) \cdot \operatorname{erfc}\left(\frac{1}{s} \cdot \ln y + \frac{3s}{2}\right), \\
 y = \frac{\sqrt{4 \cdot D \cdot t}}{r_{50}}, \quad s = \sqrt{2} \cdot \sigma
 \end{aligned}
 \tag{18}$$

Here, $\operatorname{erfc}(z)$ denotes the complementary Gaussian error function of argument z , while y and s are used as abbreviations in the formula. It is true that sand dissolution does not proceed isothermally at a constant diffusion coefficient D in a real fusion process, but the utmost importance of the grain-size distribution for a successful fusion process is nonetheless demonstrated clearly.

1.4

Primary Fabrication of Flat Glass

Toru Kamihori

Production Technology Center, Asahi Glass Co., Ltd., Yokohama-shi, Kanagawa, Japan

1 Introduction

Flat glass is ubiquitous in the modern world, from the facades of high-rise buildings to the large windows of automobiles, the solar power generation systems, and the various kinds of displays that are now integral components of daily life. Not only did these new applications cause a tremendous increase of the world production from less than 7×10^5 in the early 1960s to 59×10^6 metric tons in 2014 (then with an annual growth rate of 7%), but they have also yielded dramatic improvements in glass quality and functionalities. For a glass material that had been manufactured for 2000 years with very little change, the industrial evolution observed during the last 50 years has been incredibly rapid indeed!

As experienced by ancient Roman glassmakers, flat glass made by pouring the melt on a solid substrate has a surface that is not smooth enough to ensure good transparency. Until the beginning of the twentieth century, flat glass had for this reason to be produced out of hollow glass to keep the defect-free surface conferred by fire polish. As made in this way with either the crown or the cylinder process (Chapter 10.8), production of flat glass was very labor-intensive, restricted to relatively small sheets and subject to wastage when cut into pieces for use. Besides, it did not yield high-quality products as is obvious to anyone looking at an old window where objects are often seen distorted through the glass in which defects and streaks are also generally present as a result of the detrimental effects of temperature or composition heterogeneities that could not be avoided during the melting and forming processes.

Mechanization was pioneered from 1894 to 1916 by J. H. Lubbers at the American Window Glass company. Glass cylinders of constant diameter and wall thickness began in 1904 to be blown successfully with a well-controlled low-pressure air flow issued for 15–18 minutes from a machine that was dubbed *iron lung* [1]. Making much bigger cylinders, which eventually reached 1 m in diameter and more than 13 m in length (Figure 1), did reduce considerably cost and labor (whence the very strong Union opposition met by the new process), but did not result in consistently good quality because of the wavy surface and optical distortion induced by the flattening stage. Thanks to *updraw* processes designed in Belgium and in the United States, it then became possible in the following decade to bypass the hollow-glass step. But these processes remained discontinuous because devitrified material had to be removed periodically from the production line.

A true revolution in glass producing thus occurred when the float process was introduced in the 1950s to produce sufficiently good flat glass to make the grinding and polishing steps ensuring high-quality sheets obsolete. Production became in addition completely continuous, which allowed the productivity to be considerably increased without affecting surface quality. Because of the very large amount of glass produced, however, the float process may be impractical when production volumes are small or the glass composition has to be changed frequently. For specialties such as crown glass for niche markets or new glass for electronics markets, older processes are thus still used or new ones have been designed to achieve in particular a high flexibility of throughput and broad ranges of thickness and width.

In this chapter, we will review the various processes that have been designed to achieve these goals, beginning with the first developed ones whose interest is now only historical. The early processes are denoted as *updraw* because

Figure 1 Very large glass cylinders blown mechanically with the Lubbers process for flat-glass production [2].

the glass was drawn upward, in contrast to the *downdraw* processes, which have subsequently been developed for specialty glasses. No attention at all will be paid to the synthesis of the glass itself, which is described in Chapter 1.3. The emphasis will thus be put on the forming process and on the material parameters such as viscosity, density, heat capacity, and surface tension that control it. For more detailed descriptions, the reader will be referred to the available technical literature [1–9].

2 Overview

The main features of past and current processes are summarized in Table 1. Although updraw processes are no longer used for commodity applications, it remains worthwhile to examine their mechanisms and forming principles from a technological viewpoint. For flat-glass forming, the essential requirement is to achieve the constant desired thickness, which now ranges from around 25 mm to less than 50 μm , with the specified width at a commercially admissible cost. Additionally, a flatter and smoother surface is requested. The essential forming defects are mainly of two kinds depending on whether they are derived from locally uneven deformation or undesirable stress. The former is caused by viscosity heterogeneity of glass originating from chemical impurities

or temperature irregularity, and the latter is caused by fluctuation of forming condition or stress imbalance.

Architectural glass must, for instance, satisfy appropriate transparency and reflection, but glass for automobiles and electronics products has to meet much more demanding quality specifications even for thinner glass whose production becomes increasingly difficult.

In all forming processes, two distinct steps are involved once the glass has been melted at about 1500 °C, refined, and homogenized in the melting tank. The first is its delivery under conditions at which the temperature, thickness, and flow rate must be as stable and uniform as possible throughout its whole width at a viscosity of about 10^2 – 10^3 Pa·s (i.e. at 1200–1000 °C for soda-lime silicate). In the second step, the more viscous molten glass cooled down to a temperature at which the viscosity is 10^3 – $10^{6.65}$ Pa·s (i.e. at 1050–700 °C for soda-lime silicate) is stretched in the longitudinal direction, while minimizing simultaneous narrowing of the glass ribbon.

In both glass delivering and stretching systems, properties of the molten glass such as surface tension, gravitational force, and tensile stresses are critical factors, whereas the kinetic aspects of the process are tightly controlled by means of drawing chambers, *débiteuses*, draw bars, rolls, float baths, slots, fusion pipes, etc. Besides, heat management through variously devised heaters and coolers is another fundamental aspect because glass properties vary very strongly with temperature. In addition to physical effects, one must also take into account chemical factors such as possible devitrification and chemical reactions between the glass and other materials, which may themselves depend on glass composition.

Since annealing follows forming, the conditions of the former process are greatly influenced by those of the latter. The formed glass ribbon is cooled down and conveyed to an annealing *lehr* where the decreasing glass temperature is carefully controlled so that residual stresses caused by viscoelasticity are relaxed between the annealing and strain points (10^{12} Pa·s, 570 °C, and $10^{13.6}$ Pa·s, 530 °C, respectively, in soda-lime silicate), and breakage caused by thermal stresses is minimized upon cooling down to room temperature. Finally, optical devices are installed at the downstream part of production line to detect in the glass at room temperature any visible defects such as bubbles, stones, streaks, etc., which originate either from the melting tank or the forming process. These defects are at once clearly marked on the glass ribbon and their positions are usually electronically recorded for optimized cutting either at the end of the production line or by the user according to its specific application. For flat glass to be used in buildings, any 10 m^2 -sheet must, for instance, have fewer than three defects with a maximum size of 1 mm (which would be tantamount to finding fewer than three coins on a football field!).

Table 1 Comparison of forming processes.

Category	Process	Mechanism		Advantage	Disadvantage	Current situation
		Step 1: Preliminary forming (Molten glass delivering)	Step 2: Main forming (Stretching)			
Updraw process	Fourcault process	Glass flow toward débiteuse and upward flow through débiteuse slot	Upward drawing against gravity by pairs of rolls	Earliest continuous production Smaller investment	Quality (Draw lines) Cyclic operation	Almost obsolete for commodity applications Customized/modified process operating for specialty glass
	Colburn process	Glass flow toward drawing point and upward flow from free surface	Upward drawing against gravity by pair of knurled rolls and bending roll	Higher output Wide range of thickness	Low surface quality Complex operation	
	Pittsburg Pennvernon process	Glass flow around draw bar and upward flow above draw bar	Upward drawing against gravity by pairs of rolls	Better surface quality Longer cycle	Distortion Thickness deviation	
	Asahi process	Glass flow toward Asahi blocks and upward flow through gap between Asahi blocks	Upward drawing against gravity by pairs of rolls	Smaller investment Longer cycle	Cyclic operation	
Roll out process	Continuous double roll process	Horizontal glass flow through forehearth	Pressing by pair of rolls	Value added with patterns and wires Versatility Smaller investment	Limited applications	Popular for patterned glass, wired glass, and specialty glass
Float process	For thinner sheet (Top roll process)	Viscous flow with equilibrium thickness in upstream area of bath	Horizontally stretching by conveyor rolls and top rolls	Large-scale production (productivity) Quality (flatness) Flexibility for thickness and width	Large investment Constraint of chemical elements in glass	Widely operating in the world for various applications
	For thicker sheet(Fender process)	Viscous flow with restricted width by pair of fenders	Cooling to appropriate temperature in fender area (without stretching)	+ Thicker and larger sheet		
Downdraw process	Slot downdraw process	Glass flow toward slot and downward flow through slot	Stretching by pairs of rolls and gravity with anchored to slot	Thinner glass Small-scale production	Flatness and surface quality Limited width	Customized/modified process operating for specialty glass
	Fusion downdraw process	Glass flow through trough and over weirs, downward flow on both sides of fusion pipe	Stretching by pairs of rolls and gravity with anchored to root	Thinner glass High surface quality	Minute control required (temperature, glass flow) Constraint of liquidus viscosity	Popular for specialty glass

3 Updraw Processes

3.1 Fourcault

The first manufacturing method successfully industrialized and commercialized was invented from 1901 in Belgium by É. Gobbe and É. Fourcault and finally implemented industrially in 1912 by É. Fourcault in his family company in Charleroi. With this process, the molten glass was drawn vertically through a débiteuse into a continuous glass ribbon. The débiteuse, a rectangular refractory piece with a spindle-shaped slot at the center, was immersed into the molten glass. The molten glass flowing up from the slot was drawn upward and immediately cooled by the coolers while conveyed upward by pairs of rolls in a such a manner that its width was kept constant. The formed glass was annealed along the way and finally cut off at the top of the 8–10 m drawing tower (Figure 2). The flow rate was controlled by the immersion depth of the débiteuse, the shape of the slot, and the cooling exerted, whereas the thickness of the sheet was determined by the drawing speed.

The advantages of this process were many. Not only could production be made with several drawing machines for a single glass tank, but wide ranges of thickness (1–8 mm) and width (1.5–2.5 m) were possible for glass sheets formed with a relatively uniform thickness. In terms of disadvantages, continuous operation was impossible because of the need after about two weeks of operation to remove the devitrified glass that was accumulating around the slot of the débiteuse and on the inner surfaces of the drawing kiln. Whereas the former devitrified

Figure 2 Sketch of Fourcault process in cross section. The molten glass flows up through the débiteuse slot and is drawn upward [3].

material was causing draw lines, the latter changed the flow rate and flow pattern toward the débiteuse. In addition, it was impossible to maintain a completely stable throughput because of bubble formation at the beginning of a drawing cycle and draw-line problems and instability toward the end [1, 3–6].

3.2 Colburn

At the same time the Fourcault process was being developed, the American inventor I. W. Colburn (1861–1917) was experimenting vertical drawing without a débiteuse. His first patent was taken in 1902 but the company he founded in 1906 to produce glass went bankrupt five years later. Working thereafter for the Toledo Glass Company, which had bought his patent, Colby was eventually successful in 1913. With his process, the molten glass introduced into a shallow drawing chamber was drawn upward from the free surface, its edges being gripped and driven by pairs of knurled rolls, and cooled immediately. After being reheated by a gas burner, the formed glass was brought horizontally by a bending roll and conveyed to a horizontal annealing lehr (Figure 3). Since the surface condition and flatness of the bending roll directly determined the quality of the glass sheet, the choice of an appropriate metal as well as the surface treatment and temperature control of the bending roll were crucial. Typically, two drawing chambers were mounted on one glass tank. The 0.9–6 mm thickness range obtained was similar to that of the Fourcault process, but devitrification on the débiteuse was avoided and a much larger width of up to 4.2 m could be obtained, thanks to the horizontally conveying process. But the price to be paid was a lower glass quality because of thickness variations, optical distortions, and surface defects [1, 3–6].

Figure 3 Sketch of Colburn process in a bird's-eye perspective. The molten glass is drawn upward from the free surface and bended horizontally by a bending roll [6].

3.3 Pittsburgh Pennvernon

A process similar to that of Fourcault was developed and introduced by the Pittsburgh Plate Glass Company in 1926. In this Pittsburgh Pennvernon process, the molten glass was not drawn through a *débiteuse* but upward from the free surface right above a drawbar, which was a long and thin refractory part immersed below the glass surface. The ribbon width was kept constant because the glass was cooled by edge folks and coolers. After being annealed and cooled in the drawing tower, the glass ribbon was cut off at the top of the tower (Figure 4). The drawbar served to anchor the drawing point and to ensure uniform temperature and glass flow rate across its width. In addition, ell blocks served to homogenize the drawing temperature by keeping the glass melt covered. The operation cycle was much longer than that of the Fourcault process with a better surface quality and without devitrification complications. Typically, the thickness range was 1–8 mm with a width of up to 3.2 m, but the disadvantages were thickness variations resulting from temperature fluctuations and inhomogeneities in chemical composition caused by drawing of the glass directly from its surface [3–6].

3.4 Asahi

The most recent updraw process has been developed by Asahi Glass Company around 1970 to overcome in a new way the disadvantages of the Fourcault process [5, 6, 8]. With it, a pair of hourglass-shaped rolls, called “Asahi blocks,” is immersed into the molten glass instead of a *débiteuse*

(Figure 5). The trick then is to make the Asahi blocks rotatable to renew the parting line where the glass leaves from the refractory and devitrification takes place. As a result, much longer drawing periods of up to 2–4 months can be achieved. An additional advantage is that thinner sheets down to 1.1–0.7 mm can be produced, especially for electronics applications, with a width of 1.5–2 m, thanks to the forming stability derived from the Asahi blocks.

4 Roll Out Process

The continuous double-roll process was developed in the United States in an effort led by the Ford Motor Company to meet a growing demand from the automotive industry. As delivered from the forehearth, the molten glass was pressed to a given thickness, cooled rapidly by a water-cooled pair of rotating rolls, and then conveyed into a horizontal annealing *lehr*. The thickness was determined mainly by the gap between the rolls, whereas the output was fixed by the rotating speed of the rolls.

As made by Pilkington Brothers in the 1920s, this process was then improved to manufacture plate glass through online grinding after annealing, followed by polishing of the cut plates. The process was further developed by Saint-Gobain in the 1950s to grind *and* polish on line the glass ribbon (Chapter 10.9). Along with a waste of about 20% of the glass, very high investment and operating costs were major disadvantages of these mechanical methods, however, which in fact prompted Pilkington to develop the float process as described in Section 5.

Figure 4 Sketch of the Pittsburgh Pennvernon process in cross section. The molten glass is drawn upward from the free surface right above the drawbar immersed below the glass surface [3].

Figure 5 Sketch of the Asahi process in cross section. The rotatable Asahi blocks are immersed into molten glass instead of the *débiteuse*, and enable the parting line to be renewed where devitrification takes place [6].

Because the float process was not designed at all for patterned and wire-reinforced glass, the continuous roll out process, with which these products have been produced since the 1920s, has escaped oblivion (Chapter 10.9). Thanks to its versatility and facility for customization, it has even found new special applications, for instance, to make cover glasses for solar cells with excellent light diffusion through patterned textures on the surface. Usually the pattern is impressed on the lower surface by the lower roll, which is engraved. Generally the thickness range is 2–7 mm for the patterned and 8–25 mm for the polished glass.

Figure 6 Sketch of single-pass wire roll out process (upper part insertion process). The wire is inserted into the molten glass, which is pressed and cooled by rotating water-cooled rolls [8].

As to wire-reinforced glass, it is produced in two ways depending on whether the wire is simply inserted into a molten glass (single-pass process, Figure 6) or sandwiched between two glass layers (double-pass process). Although more complex, the latter process has advantages over the former in terms of larger output, wider width, and higher quality, and better suitability for subsequent conversion into polished wired glass because the wire mesh is always precisely located at the center in the thickness direction [1, 3–8].

5 Float Process

5.1 Principle

When it was invented in the 1950s, the float process turned out to be an epoch-making method to produce flat glass with a smooth surface without any additional polishing. Its production cost was low enough to make possible an extensive use of the material in buildings and automobiles, which is one of the hallmarks of current civilization. The basic process of making flat glass on a molten metal was in fact patented in various ways as early as in 1848 in England by H. Bessemer, of steel-converter fame, and then several times in the United States by W. Heal and J. H. Forrest (1902 and then in 1925), and by Halbert K. Hitchcock (1905 and 1925), but a great many technical problems had to be solved before the process could be made practical. Through a seven-year expensive research program of Pilkington Brothers in the United Kingdom, which in its last stage included 13 months of production that had to be discarded, all these problems had eventually been overcome in July 1958 by a team led by L.A.B. Pilkington (no relationship with the Company's owners) and K. Bickerstaff. The following year it

even became possible to produce with the same process the distortion-free glasses needed for mirrors, thus abolishing the long-standing distinction between window and polished-plate glass (Chapter 10.9).

Although the float process became continuously profitable only in 1963, the previous year it began to be licensed all over the world by Pilkington Brothers in rapidly expanding markets. Within a decade, the good optical quality of float glass resulted in a vanishing share for other sheet- and plate-glass processes. As of 2015, more than 400 float plants are operated worldwide, units being up to about 500 m long (Figure 7). With a typical size of about 25×60 m, melting tanks are bigger than Olympic swimming pools to produce 600 metric tons (and even up to 1300 tons in the biggest plants) of flat glass per day with an investment cost ranging from 70 to 200 million dollars or euros, depending on actual size, location, and product complexity. As for the inflation-adjusted production cost (cf. Chapter 9.6), it has been almost continuously decreasing by a factor of 4 from 1965 to reach today a range of 200–300 dollars or euros per ton (Chapter 9.6), raw materials and energy accounting both for about 20% of it.

When a molten glass is poured onto a clean molten metal bath, it floats, thanks to its much lower density, spreads out, and thins to the point where the gravitational forces and the surface tensions among the glass, molten metal, and atmosphere are in equilibrium to reach the so-called equilibrium thickness. The lower and especially the upper surfaces of the molten glass are fire-polished, perfectly flat, and parallel except at the edges. The float process is based on this principle. Among metals or alloys

that are liquid between 600 and 1050 °C, the relevant temperature range for glass forming, pure tin was the obvious choice because of its low melting temperature of 232 °C, high density of about 6.5 g/cm^3 at 1000 °C, low vapor pressure of about 10^{-7} atm at 1000 °C, high boiling point of 2602 °C, low reactivity with silicates in the metallic state, and not too high cost (about 20 dollars/kg as of 2015).

The aforementioned equilibrium thickness T_e is given by

$$T_e^2 = 2\rho_t(S_{ga} + S_{gt} - S_{ta}) / [g\rho_g(\rho_t - \rho_g)], \quad (1)$$

where S_{ga} , S_{gt} , and S_{ta} are the surface tensions at the glass–atmosphere, glass–molten tin, and tin–atmosphere interfaces, respectively, g is the gravitational constant and ρ_t and ρ_g are the density of the molten tin and glass, respectively (Table 2). For soda-lime silicate glass floating on clean molten tin under a nitrogen-hydrogen atmosphere, T_e is 6.9 mm (Figure 8), a thickness that is actually insensitive to small changes in the chemical compositions of the atmosphere, metal bath, or glass [1, 3–9].

5.2 Float Bath

The float bath contains several metric tons of molten glass. It is a large unit with a length of up to more than 50 m enclosed by a steel shell that is lined with thick insulating and nonreactive refractory materials and holds a pool of molten tin whose depth is 50–100 mm and total amount is up to more than 200 metric tons kept at temperatures decreasing from about 1000 to 600 °C from the

Figure 7 Overview of a float-glass plant (scale not right: size of the right-hand side, for instance, much exaggerated) <http://www.glassforeurope.com/en/industry/float-process.php>

Table 2 List of symbols regarding equilibrium thickness mechanism.

Symbol	Denotation
T_e	Equilibrium thickness
ρ_t	Density of molten tin
ρ_g	Density of molten glass
S_{ga}	Surface tension at glass–atmosphere interface
S_{gt}	Surface tension at glass–molten tin interface
S_{ta}	Surface tension at tin–atmosphere interface
g	Gravitational constant

**Figure 8** Equilibrium thickness of floating glass on the molten tin when the gravitational forces and surface tensions are balanced [3].

hot to the cold end (Figure 9). A reducing gas mixture made up of 2–8% hydrogen and 98–92% nitrogen is supplied at a high rate of the order of $10^3 \text{ m}^3/\text{h}$ from above to the bath to prevent oxidation of the molten tin and to maintain a positive pressure difference with the atmosphere at the bath exit where leakages are highest. The heaters, coolers, and other devices are installed and inserted in the bath. The molten glass is continuously supplied from the furnace conditioner via a canal where its flow rate is precisely controlled by an adjustable gate called a tweeel. It arrives to a ceramic spout lip, which is an inlet of the float bath, through which it falls freely onto the molten tin. After many years of struggle at Pilkington Brothers to achieve excellent quality, the design and engineering of the inlet area were an outstanding invention to force the contaminated molten glass in contact with the refractory lip to flow outwardly so as to be brought forward at the outer edges of the ribbon [9].

Once poured onto the tin bath with a thickness of about 50 mm, the glass spreads out and thins to its equilibrium thickness in the upstream area in the float bath. As formed to the required thickness and width in the forming area (see Section 5.3), the glass ribbon is taken

out from the bath either to receive appropriate reflective, low-emissivity, solar-control, self-cleaning, or other specific coatings (Chapters 6.7 and 6.8) or to enter directly the annealing lehr at the temperature at which the viscosity is about $10^{10} \text{ Pa}\cdot\text{s}$ (i.e. about 600°C for soda-lime silicate). At the end of the lehr, whose length can reach 120 m, the ribbon is finally cooled down to room temperature and brought into the cutting area. Whereas both edges are cut out (to be recycled as cullet) because of the imprint left by the top rolls, the ribbon itself is cut either according to customers' specifications or as standard sheets, for instance, $6.0 \times 3.21 \text{ m}$ in Europe where tools used in the flat-glass transportation industry have been fitted to this size (which, by the way, is too large to allow flat glass to be shipped in containers).

5.3 Thinner (Top-Roll Process) and Thicker (Fender Process) Glass Ribbons

For forming thin sheets, the molten glass with its initial equilibrium thickness in the upstream area in the bath is subjected at the same time to longitudinal and lateral forces. The former are exerted by conveyor rolls that stretch the ribbon from the annealing lehr and pull it at a typical speed of up to 25 m per minute. The latter are exerted outwardly on the ribbon edges by pairs of top rolls, which are water-cooled rotating gears, to reduce the narrowing of the glass ribbon because the imposed longitudinal stretching reduces not only its thickness but also its width (Figure 10a). In parallel, the glass ribbon is cooled down to prevent it from returning to its equilibrium thickness until its width is constant at the end of the forming area. In view of the fundamental influence of viscosity within the glass ribbon upon stretching and thinning, the temperature distribution and the top-roll operations must be controlled very tightly to ensure a good forming quality. Besides, keeping the glass ribbon as wide as possible is important to maximize productivity.

For producing float glass thicker than the equilibrium thickness, a pair of water-cooled carbon fenders serves as slipping guides to the flowing glass in the bath (Figure 10b). The glass thus proceeds with a restricted width and a large thickness. As it passes down the fender area, the effects of gravitational forces and surface tensions make both its upper and lower surfaces flat and thickness uniform. The glass is then cooled to an appropriate temperature in the downstream area of the fender where its viscosity is high enough not to allow width changes. In contrast to what is taking place in the top-roll process, stretching is not significant at all and there is no drive to return to the equilibrium thickness because there is no glass–tin–atmosphere interface in the fender area.

Figure 9 Sketch of the tin bath part of the float process: (a) on vertical plane along centerline; (b) on horizontal plane. A reducing nitrogen–hydrogen gas mixture is supplied from above. Heaters and coolers are installed [10].

Figure 10 Sketch of the float process: (a) for sheets thinner than the equilibrium thickness, where the glass is stretched, from its edges by top rolls and from its downstream part by conveyor rolls; (b) for sheets thicker than the equilibrium thickness, where water-cooled carbon fenders serve as slipping guides to glass flowing [7].

5.4 A Complex Industrial Problem

In spite of the simplicity of its principles, the float process is not readily implemented because flow in both tin and glass and heat transfer among tin, glass, and the radiative field are really complex processes. Glass

forming is mainly determined by parameters such as the glass flow rate, conveyor speed, rotating speed and angle of top rolls, and by the viscosity distribution within the glass ribbon. It goes without saying that the viscosity of the glass strongly depends on temperature, but the temperature distribution in the bath is itself influenced

by radiative heat transfer, the flow of molten tin, and the glass forming conditions. Radiative heat transfer is predominant in the bath at temperatures higher than 600°C , but the flowing molten tin also contributes markedly to heat transfer as a result of its high heat capacity, high thermal conductivity (about 50 times higher than that of the glass), and low kinematic viscosity (about 8 times lower than that of water), whereas the glass flow carries a large amount of convective heat. On the other hand, molten tin flows by traction from the glass ribbon (i.e. velocity distribution) and buoyancy convection (i.e. temperature distribution in the bath). In order to understand forming conditions, one thus needs to understand the whole set of processes taking place in the bath since glass forming, heat transfer in the bath, and flow of molten tin affect one another in a very complex manner.

As summarized by C.K. Edge [4], the float bath thus is “a remarkable entity which, although first envisioned as a finisher of glass surfaces, also functions as a container, a conveyor, a forming unit, a chemical reactor and a heat exchanger.” In view of this complexity, valuable information has been drawn from mathematical simulations not only of the glass forming mechanisms, but also of the temperature field and the mutually related dynamics of the molten tin and glass ribbon. As examples, calculations with finite-element methods of the thickness contour over the glass ribbon and of the lateral thickness distribution of the ribbon at the bath exit are shown in Figures 11 and 12 [10]. The rather good agreement of such model values with the temperatures, thicknesses, or ribbon shapes that can be measured on line illustrates how simulations can be used to optimize the operating conditions, to design new facilities, and to check new ideas for process improvement and development.

From a chemical standpoint, potentially annoying impurities are oxygen from leaks or the $\text{N}_2\text{--H}_2$ gas mix, and sulfur originating from the molten glass. Both deteriorate productivity and glass quality if they induce alteration on the bottom surface of the glass caused by reactions with tin, and contamination adhesion on top and bottom surfaces (Chapter 5.6). In the so-called oxygen and sulfur cycles (Figure 13), SnO and SnS vapors form, condense, and precipitate, the former as SnO_2 and the latter as SnS (which is ultimately reduced to Sn particles). Thanks to extensive research, however, these impurities are now carefully managed through monitoring, sealing, cleaning, atmosphere controlling on flow and pressure, etc.

5.5 Trends in Float Production

The float process is advantageous because it yields excellent flatness, high flexibility with regard to thickness and

Figure 11 Shape and thickness distribution of a 2 mm thick float-glass ribbon calculated with an integrated glass-forming model [10]. Forming (i.e. shape, thickness, and velocity distributions of the glass ribbon) and the flow of molten tin are first calculated for a given temperature distribution of the glass ribbon. Heat transfer (i.e. the temperature distribution) in the float bath then is simulated, and the whole calculation is iteratively repeated until convergence is reached for the three interrelated mechanisms.

Figure 12 Simulated thickness distribution at the exit of the bath for 2 mm thick glass ribbon. The lateral distance is normalized [10].

width, and high productivity owing to completely continuous operation during the whole lifetime of the melting furnace, which can now reach up to two decades. Ever since its conception, plenty of technological improvements have been conducted for achieving higher throughput, larger width, and higher still quality, the thickness currently extending down to less than 0.4 mm and up to around 25 mm.

Originally the float process was designed to produce glass sheets for architectural window and mirrors. Since the 1970s, the technology has evolved to meet other demands, especially that emerging from automotive

Figure 13 The complex interactions of impurities with the atmosphere, tin bath, and glass ribbon in the float process: (a) oxygen cycle; (b) sulfur cycle. Source: After Pilkington [9].

market for higher optical quality and thinner sheets along with higher throughput to keep production costs reasonable. In addition, the float process has contributed to the growing solar generation market with products such as mirrors for solar power systems and cover glasses for photovoltaics.

In the early 1980s, the float process achieved production of ultrathin glass of less than 1.1 mm for twisted nematic (TN)/super TN (STN) liquid crystal display (LCD) substrates, touch panels, and other electronics products with a remarkably high quality for flatness, thickness constancy, defect level, etc. Beginning in the 1990s, the float process has been producing flat glass of various kinds of compositions other than the traditional soda-lime silicate. Examples are alkali-free glass for thin film transistor (TFT) LCD substrate, high strain-point glass for plasma display panel (PDP) and solar panel substrates, specialty glasses for heat-resistant products, hard

disk drive (HDD) substrates, and other products such as touch panels and display covers that are then chemically strengthened.

6 Downdraw Processes

6.1 Slot Downdraw

It was for forming thin glass sheets that the slot down-draw process was developed in the 1940s. As driven by pairs of rolls, the molten glass is pulled downward through an accurately dimensioned narrow slot, made of platinum, which is fixed at the bottom of the fore-hearth. The glass sheet pulled from the slot is then gripped on its edges to prevent narrowing (Figure 14). The suitability of this process for making thin glass stems from the fact that a viscous molten glass can be pulled downward with a higher speed than if it were just subjected to free fall [3, 7, 11].

6.2 Fusion Downdraw

The slot downdraw process has disadvantages in terms of imperfect flatness and other defects caused by slot deformation and foreign contamination on the inside of the slot. It was to overcome them that the fusion downdraw process was developed by Corning [3, 5, 7, 11]. As sketched in Figure 15, the well-stirred molten glass is delivered through a conduit tube to one end of a rectangular trough that is the upper part of a fusion pipe. The molten glass flows over the weirs uniformly along the full length of the trough and then runs down on both sides of the fusion pipe. Two glass streams join and merge together at the "root," which is a bottom apex of the fusion pipe. A pair of rolls grips the edges of the glass sheet just below the root to prevent the sheet from becoming narrower as it is stretched downward. The glass sheet is then cooled down while its edges are still held by pulling rolls as it proceeds through a vertical annealing lehr, and is finally conveyed to the cutoff station. The distinguishing advantage of the fusion downdraw process thus is that the glass is formed without touching anything except air so that one obtains a smooth and defect-free fire-polished surface. To be achieved, however, this result requires a highly homogeneous molten glass and a minute control of the distribution of glass temperature and flow.

Since the 1960s, the fusion downdraw process has produced photochromic glass, heat-resistant glass, and glass for chemically strengthening. It provides ultrathin specialty glass of less than 1.1 mm thickness used for electrical capacitors, microscope slides, optical filters, touch panels, micro electronic mechanical systems (MEMS),

Figure 14 Sketch of slot downdraw process in cross section. The molten glass is pulled downward through a narrow slot driven by rolls [7].

substrates of TN LCD, and thin film solar cells. Besides, production of alkali-free glass for TFT LCD substrate was started in 1984 by Corning. Although the specifications are in this case much more severe, the fusion glass can also be used for TFT LCD substrate without polishing,

thanks to its excellent surface quality. To meet the market demand for larger size substrates, the width has been extended up to around 3 m. In addition, the downdraw process is applied to specialty glass for emerging chemically strengthened products such as touch panels and display covers.

7 Perspectives

Over the years the demand for flat glass has paralleled the growth of the global economy. In addition to architectural applications, the automotive, solar energy, and electronics especially flat panel display (FPD) application markets have all been at the same time growing and an important source of new, value-added products (Chapter 6.10). Recently, glass sheets for chemically strengthened components such as cover glass for displays and ultrathin glass for touch panels have emerged as important products driven by the explosive diffusion of mobile phones and tablets with touch sensors [12]. These trends are supposed to continue and affect markets such as appliance, transportation, interior architecture, and many others. The important role of flat glass keeps increasing in these domains as well as in the field of information and communication, optics, healthcare, and so forth. Further improvements will thus be made to meet new specifications and respond to various market demands. From an industrial perspective, however, not only the cost and quality of the glass itself but also controllability, investment size, yield, delivery time, versatility, cost of post-processing, and other factors of the manufacturing process have to be taken into consideration for each application. Therefore, an overall and comprehensive understanding of the forming process remains a key issue.

Figure 15 Sketch of fusion downdraw process in a bird's-eye perspective. Molten glass flows over weirs and run down on both sides of fusion pipe. Two glass streams join and merge together at the root and are stretched downward [3].

For new applications, work is in particular being conducted on ultrathin flexible glass (0.2 mm–30 μm) and on rolled glass for flexible display, OLED lighting, and organic thin-film solar cell to take advantage of unique features of glass such as bendability, impermeability to gas, transparency, surface quality, chemical and thermal durability, and so on [13]. Such products are not yet on the mass market because the fundamental technologies are not mature, but flexible and rolled glasses are nonetheless expected to come out in the near future. The applications to the field of health care, electrical and optical packaging, MEMS, and so forth are anticipated to become more popular as well [14]. The relevant information can be found on the websites of glass manufacturers.

Two directions for development of the forming process can be followed. One is to improve further currently existing processes in terms of flatness, thickness, width, productivity, controllability, cost, versatility, facility life-time, etc. The other direction is to add values through online introduction of other features such as coating and surface treatment (cf. Chapters 6.7 and 6.8). A closer match and harmonization between forming process and glass composition and properties might be also attractive.

As for forming commodity glass, invention of a novel process surpassing float with regard to energy consumption and investment costs would be desirable. For specialty glasses, innovative processes with higher quality and lower cost will of course also be sought after. Advances in basic science, simulation methods, sensing procedures, and information technology are presumed to become still more important either in operation and engineering or in development and innovation. Moreover, newly developed materials could make other innovative progress possible. In this respect, could unprecedented innovations based on novel mechanism make the processes described in this chapter obsolete in a near future? Their advantages should be considerable to write off the capital invested in current production plants all over the world. But would those innovations give rise to new applications and create new markets? A never ending challenge will change the world [15, 16].

1.5

Fabrication of Glass Containers

Christian Roos

IPGR – International Partners in Glass Research, Bülach, Switzerland

1 Introduction

At the beginning of the twentieth century, glass-container manufacturing still was a strenuous business, involving much manual labor and sweat. In 1903, Michael J. Owens developed in Ohio the world's first fully automatic glass-forming machine (Chapter 10.9). The concept consisted of a rotating machine that sucked glass from a pool of melt into forming molds. A preform of the final container (the so-called “parison”) was first produced, and then transferred into a second mold where the parison was blown to its final shape to form the container itself. This truly revolutionary concept gave major advantages over semiautomatic methods since it cut labor costs by 80% and also led to the end of child labor in glass-manufacturing companies. But this concept still had its drawbacks because the machine itself was expensive and cumbersome and a true monster of tons of rotated, lowered, and lifted metal.

In 1915, Karl E. Peiler and F. Goodwin Smith established a fully automatic press-and-blow rotary machine, which was fed with glass from above by an automatic paddle-needle gob-feeder (Chapter 10.9). Although this design resulted in a much less complex forming cycle, the machine was still a rotating system that involved again much mechanics and moving metal. And, most importantly, as soon as one section of a rotating machine experienced any problem, the machine as a whole had to be stopped. Hence, yield was significantly decreased when the complete machine had to be paused because only one section was experiencing problems.

With gob-feeding getting more and more sophisticated, a search began for a more efficient forming process. In 1924, F. Goodwin Smith and Henry W. Ingle developed a totally new concept for automated glass-container forming: the IS-machine, where “IS” stands for *Individual Section*. The machine sections were no longer arranged in a circle but in a row. This meant that each section of the forming machine operated independently from the others. Hence, if failure occurred in one section, just this section and not the complete machine had to be stopped and fixed. This made production much more efficient and flexible. Production speed and container quality also were greatly increased.

With 4 individual sections in the first IS-machine, the concept was soon improved and enhanced from initially 4 single gob sections (in total, therefore, 4 containers in one complete machine cycle) to nowadays 12 section-systems with multi-gob delivery to each section. In the most recent form, IS-machines can consist of 12 sections, with 4 forming molds per section (quad-gob system), summing up to 48 containers produced in one machine cycle.

Looking at a modern IS-machine, however, one should nonetheless recognize the basic features that were designed when the concept was first developed. As shown in Figure 1, one section is made of the following zones, which will be explained more in detail later in this chapter:

- 1) Delivery equipment, consisting of scoop, trough, and deflector.
- 2) Blank-side with plunger, neck-ring, guide-ring, mold-halves, and baffle.
- 3) Invert with invert-arm holding neck-ring and guide-ring.
- 4) Blow-side with bottom-plate, blow-head, and mold-halves.
- 5) Take-out with tongs, dead-plate, and pusher to conveyor belt.

Figure 1 Schematic overview of one section of an Individual-section machine (here Narrow-Neck Press & Blow process, double-gob set-up).

Several major improvements have been implemented in the forming process since its beginnings. We will, for instance, describe how, following the *Press & blow* (PB) and *Blow & blow* (BB) processes, the *Narrow-neck press & blow* (NNPB) process has recently met with much success because of its more efficient forming. And it should also be stressed that the original pneumatic control of IS-machines has given way to servo-electric devices with which higher precision and reliability has been achieved.

2 Principles of Glass-Container Forming

Before a glass can be formed, it usually has to be melted out of the respective raw materials. The melting of container glass bears some peculiarities such as a high usage of foreign (external) recycled cullet or auxiliary devices such as batch and cullet preheaters. Because these features and the basics of the melting of container glass are described elsewhere in Chapter 1.3, we will focus solely on forming.

Glass containers for mass-market are formed with the aid of molds in which the molten glass is blown or pressed. The forming process consists of two steps. First a “parison” is made in cast-iron “blank-molds.” Then, in the second step, this parison is formed into the final container in “blow-molds” that are made of either cast iron or aluminum bronze.

2.1 Heat Management in Glass-Container Forming

A basic feature of the forming process is that it is highly non-isothermal. On the one hand, temperature differences over the dimensions of the glass component are present and on the other, the glass experiences a great change in temperature and thus in glass properties. As a result, the forming process has of course to be designed to cope with these changes, which are the largest for viscosity.

When the gob enters the mold in the first forming step, it has a bulk temperature of about 1050°C . The mold itself has a temperature of $450\text{--}520^{\circ}\text{C}$ at the end of the parison forming cycle, depending on forming conditions and container type. The glass–metal interface temperature T_C , which is a very important parameter for the forming, is almost constant (Figure 2) because of the short contact time t of only a few seconds between the gob and mold material. It depends on the temperature of the glass T_1 , on that of the contact material (mold) T_2 , and on the thermal conductivity λ , heat capacity C_p , and density ρ of both the glass and the mold material [1–3].

For soda-lime-silica glass, at the relevant temperatures these values can be taken as $\lambda \approx 10 \text{ W/m}\cdot\text{K}$, $C_p \approx 870 \text{ J/kg}\cdot\text{K}$, and $\rho \approx 2500 \text{ kg/m}^3$. For laminar cast iron, appropriate parameters are $\lambda \approx 55 \text{ W/m}\cdot\text{K}$, $C_p \approx 500 \text{ J/kg}\cdot\text{K}$, and $\rho \approx 7300 \text{ kg/m}^3$. From these values, one can estimate T_C with:

Figure 2 Temperature gradients and interface temperature between contact-material and glass over time.

$$\frac{T_1 - T_C}{T_C - T_2} = \frac{\sqrt{(\lambda \cdot c_p \cdot \rho)_{\text{mold}}}}{\sqrt{(\lambda \cdot c_p \cdot \rho)_{\text{glass}}}} \quad (1)$$

One finds in this way that temperatures of 1050°C for the gob and 470°C for the blank mold yield an interface temperature of ca. 614°C if no oxide layer resulting from corrosion of the mold is present and if the heat balance of the blank mold is correctly managed.

A certain cooling of the glass during the forming process is mandatory to achieve a stable enough product that does not lose shape in subsequent processes (handling, coating, etc.). If cooling is not applied correctly, too low a viscosity will prevent the parison from maintaining its shape and, thus, correct dimensions from being achieved and the final container from conforming to its specifications. In glass-container forming, this stabilization is realized, thanks to the surface layer of the parison that cools down through contact with the mold. Heat transfer thus is, in general, an important aspect in the forming of container glass. Not only large amounts of heat need to be removed from the glass, but heat transfer must be controlled locally to avoid internal tension that would build up if the shrinking rate were variable throughout the glass. The average heat transfer Q_{0-t} during the short contact period t between the glass and mold can be calculated according to

$$Q_{0-t} = \frac{\lambda_g \cdot \lambda_m}{\lambda_g \sqrt{\lambda_m / (c_p \cdot \rho)_m} + \lambda_m \sqrt{\lambda_g / (c_p \cdot \rho)_g}} \cdot \frac{2(T_1 - T_2)}{\sqrt{\pi \cdot t}} \quad (2)$$

where m designates the mold and g denotes glass properties. With the aforementioned parameters, one, for instance, finds a very large average heat transfer of 647 kW/m² for a typical forming cycle for which $t = 6$ seconds.

2.2 Interface Interactions in Glass-Container Forming

Whenever a glass container is formed through contact with a solid material, such as a mold or roller, the interface between the two bodies is a crucial point. From the preceding presentation, it appears that problematic situations occur when the interface temperature is either too high or too low.

If cooling of the mold is not rapid enough in relation to the gob temperature, the interface temperature between the gob and mold increases and at a certain point the glass begins to stick to the mold. The sticking temperature has a lower bound at which the glass still can be separated from the mold without significant damage. Nevertheless, reaching this lower bound leads to process failure because sticking of the glass causes a bad loading and an inhomogeneous temperature distribution, which themselves give rise to defects in the final container. At the upper sticking temperature, removing the glass from the contact material inevitably leads to damages of the glass, like checks or torn-out pieces.

The glass sticking temperature is widely independent of the type of the contact material. It is basically a function of the interface temperature T_C , but surface conditioning of the contact material may play a role as well. Sticking appears when the viscosity of the glass at the interface becomes lower than 10^{8.8} Pa·s [4, 5]. For an average container-glass composition that means sticking begins to take place when the interface temperature T_C between the gob and mold becomes higher than ~ 645°C.

The interface temperature of about 614°C calculated above is lower than the sticking temperature. However, it can easily happen in production that this temperature increases locally such that sticking of the glass does occur. This may happen because of changed cooling conditions, cooling failure, or the growth of an oxide layer on the molds, which significantly decreases thermal conductivity.

The friction coefficient μ between the glass and contact material plays a crucial role during forming. A low dynamic friction between the contact material and the glass favors a good gob-loading and glass-forming. Often the molds and the finish equipment are coated with a lubricant that decreases the friction. This so-called swabbing process is widely used in glass-container manufacturing. The swabbing lubricant mainly consists of graphite with various additives. Periodically, the molds are swabbed automatically by robot or by human hand to allow precise and stable forming. The swabbing intervals depend on the respective machine setup and container produced and can range between 15 minutes and several hours. The effect of swabbing on the friction coefficient is a temporary decrease in friction as well as a change in the heat-transfer characteristics between the glass and mold.

There are also different permanent and nonpermanent coatings available that can be applied to the mold and forming equipment to extend or even avoid the swabbing. Important physical aspects of gob-loading, including models of the mechanics of gob/blank-mold interaction and of dynamical friction, have been extensively discussed in papers to which we refer for further details [e.g. 6, 7].

2.3 Deformation Rates in Glass-Container Forming

As already pointed out, in container-glass manufacturing, the gob is first formed into the parison, and then the parison into the final container. The (de-)formation of both the gob and parison depends on the actual viscosity of the glass. A low forming- or interface-temperature leads to a high viscosity at the glass surface. Hence the glass surface starts to get “brittle.” If such a glass is then subjected to high deformation rates, as it happens not only upon pressing and blowing but also earlier in the process upon gob-cutting, it can experience too high tensile or shear stresses. The critical tensile stress σ_c (in MPa) that a hot soda-lime-silica glass can sustain at a given temperature T may be estimated from an empirically derived correlation [8]:

$$\sigma_c = \frac{4.8 \cdot 10^3}{\sqrt{T}} \quad (3)$$

Hot fracture occurs if the tensile stresses exceed this critical value. The maximum velocity $v_{\max}$ at which a glass container with a thickness d can be formed at viscosity η without experiencing hot fracture can be approximated by:

$$v_{\max} = \frac{\sigma_c \cdot d}{4\eta} \quad (4)$$

One thus concludes that at temperatures of about 1000°C, deformation velocities of ca. 500 m/s are, for instance, possible without hot fracture for a 2 cm-thick soda-lime-silica glass layer. At 900°C, the maximum allowed velocity is already down to 100 m/s and is lower than 10 m/s at 800°C. Below 700°C the risk of defects caused by hot fracture becomes significant. Because usually such defects cannot be inverted (“healed”) in later forming steps, care must be taken to prevent them from appearing.

3 Glass-Container Forming Processes

3.1 Glass Composition

For cost reasons, glass containers are made out of soda-lime-silica glass whenever special constraints do not

apply. An exception is, for instance, laboratory ware for which borosilicate glass is used instead (Chapter 7.7). Even though the forming process needs to be adapted to account for the specific properties of each glass type, the principles at work are similar for given kinds of containers. Three different forming processes are applied, namely BB, PB, and NNPB. Their main differences concern blank-side forming where the parison is made, the subsequent forming steps to make the final container being identical. As a matter of fact, many containers can be produced with more than one process so that there is much overlap between them in terms of product range.

3.2 Blow & Blow Process

The BB process is the oldest and remains still widely used in manufacturing of large and heavy containers such as wine or sparkling wine bottles. The gob is loaded into the blank mold, often via a funnel (Figure 3a). After loading, the mold is closed with a baffle and a settle-blow is applied from above through the baffle (Figure 3b). The settle-blow presses the glass gob deeper into the mold and down to the finish equipment, which basically consists of a neck-ring, a guide-ring, and a short plunger. On loading, the plunger is in upper position. In this very first step, the opening, sealing surface, and thread (if present) are thus formed before the bulk of the container itself, which represents an important difference with respect to the other forming processes.

In the current IS-machines, the loading speed of the gob is often so high that the finish is already formed at the gob-loading step, which would make the settle-blow unnecessary for the finish forming. This step is nonetheless maintained in the process to guarantee a constant heat transfer between the glass and the blank, from cycle to cycle, before counter-blow. During settle-blow, a vacuum can be applied through cavities in the molds to support the parison and finish forming. Some modern BB IS-machines work without a funnel. They control the switch between settle-blow and counter-blow by a valve in the baffle to exhaust the compressed air that is used for settle-blow.

After settle-blow, the baffle is quickly lifted, the funnel is removed, and the baffle settles again and closes the blank-mold completely. A counter-blow is applied from the down side through the formed finish, blowing the glass fully into the mold shape and forming the parison (Figure 3c).

This two-step blowing process with settle-blow and counter-blow on the blank-side causes an inhomogeneity in the container because of different contact times between the glass and the mold above and below the loading line. Such an inhomogeneity can be seen as a horizontal, optical streak in the body of the containers. It is called

Figure 3 (a–d) Blow & blow process, blank-side.

settle- or feeder-wave and can be reduced in several ways, but not fully avoided. When looking at a final container, the existence or nonexistence of a settle-wave thus indicates whether or not the container has been produced with the BB process.

After the parison has been formed, the baffle is removed (Figure 3d), the mold opens, and the parison is transferred via the invert mechanism to the blow-side.

The final forming of the container is in principle the same for all three forming processes. The following description will thus apply to all of them. When transfer to the blow-side is over, the parison lengthens into the blow-mold as determined by its viscosity and the machine parameters. This causes the outside of the parison to be reheated by the heat stored in the hot inside and temperature to homogenize within the parison (Figure 4a). This reheat is essential to ensure that the container is to be precisely formed to its intended shape. The blow-mold is

then closed, leaving the finish outside. The invert-tongs open and the container is released from the invert. Directly after releasing, the blow-head with a blowing-tube is placed on top of the finish (Figure 4b). Through this blow-head, the final-blow is applied, giving the parison the final shape of the container (Figure 4c). Strictly speaking, the reheat ends when the final-blow is triggered.

After the container has been released by the blow-mold, a take-out grips it by its finish (Figure 4d) and places it over a dead-plate through which air is blown from below to cool it further. Finally the container is transferred via a pusher onto a conveyor belt.

3.3 Press & Blow Process

The PB process is used for wide-mouth containers of all weights, such as jars and baby-food containers. It differs

Figure 4 (a–d) Forming of the final container at the blow-side (same for all processes).

significantly from the BB process at the blank-side. After loading the gob (Figure 5), the blank-mold is closed fully by the baffle and a plunger presses in an upward movement the glass from below into the mold (Figure 5b). The plungers usually are made out of tungsten carbide (WC) or another hard metal to ensure a long lifetime. In contrast to BB-forming, the process causes the finish to be formed at the end of the blank-mold process (Figure 5c) and no disturbance such as settle-wave is introduced into the parison because it is formed by a single (smooth) motion at the blank-side. As in BB, the baffle is removed after the parison has been formed, the mold opens (Figure 5d), and the parison is transferred to the blow-side to get its final shape as described above.

3.4 Narrow-Neck & Blow Process

The NNPB process is mainly used for lighter containers such as beer bottles, small water and juice containers, and other lightweight containers. It is the most advanced forming process because it yields not only the highest machine speeds but also a homogeneous glass distribution in the final container. It is similar to the PB process in that the gob is not blown into the parison but pressed via a plunger. After loading the gob (Figure 6), the mold is closed fully by the baffle and a plunger smaller in diameter than in PB presses in an upward movement the glass into the mold (Figure 6b). The plungers are also made out of tungsten-carbide. As with PB, the finish is formed at the end of the blank-mold process (Figure 6c). Again, the baffle is removed after the parison has been formed,

Figure 5 (a–d) Press & blow process, blank-side.

the mold opens (Figure 6d), and the parison is transferred to the blow-side.

Restrictions in usage of the NNPB process are due to the plunger dimensions and finish openings and the corresponding cavities pressed into the parison. The parisons are usually shorter for NNPB than for BB if the same final container shape is to be produced (e.g. a 0.33 l beverage bottle). Another significant difference between NNPB and BB is that the required gob temperature is from around 20 to 50°C higher in NNPB because of difficult pressing conditions. This difference in consequence leads to different thermal requirements during the process in terms of mold-cooling and reheat-timing.

4 Making of the Gob: Forehearth, Feeder, and Shears

Most forming processes take place at a viscosity of 10^2 – 10^4 Pa·s. Hence, for soda-lime-silica containers, the glass

needs to be cooled from melting and fining at ca. 1500°C and a viscosity of 10 Pa·s down to ca. 1050°C and a viscosity of 10^3 Pa·s. This quite demanding task is accomplished in the forehearth. The forehearth is directly connected to the working-end and ensures the required homogeneity of the glass while bringing it to the desired temperature and viscosity.

After the forehearth, a feeder enables glass-portioning and gob pre-shaping (Figure 7). It consists of a refractory tube and one or more plunger(s) that are moving periodically up and down. The tube is rotating to homogenize the melt in this final stage. With each upward stroke of the plunger, the glass stream is released from the shear blades in order to cut a gob without having a glass stream loaded on top of these shears. For a single-, double-, triple-, or quad-gob setup, the respective number of plungers operates simultaneously in the feeder, hence as many openings in the orifice ring are required. The final gob shape is influenced by the sizes of the orifice ring and plunger, and by the shape, height, and motion profile of the plunger.

Figure 6 (a–d) Narrow-neck press & blow process, blank-side.

Figure 7 Cross section of a modern feeder (double-gob setup).
Source: Courtesy Bucher Emhart Glass.

The originally continuous glass stream is cut by the shears right after it has been “pre-shaped” by the feeder and plunger and has passed through the openings of the

orifice ring. The gob needs to be completely separated from the glass stream by the shears to prevent any glass fibers from being attached to it. Any misaligned or poorly operating shear will result in shear marks and, consequently, in defects in the final container. For shears, the materials most commonly used are steel (cheap, but short-lived) and hard alloys such as WC (more expensive, but long-lived). In all cases, the shears are cooled by a shear-spray, a mixture of water and cooling fluids.

5 IS-Forming Machine

5.1 General Principles

Rotational forming machines are nowadays used only in some rare cases. The principles of glass-container forming will thus be described for IS-machines, with which almost glass containers are made. Derivatives of the IS-machine such as the Emhart RIS and Heye H 1–2

machines have been developed in the past but are hardly in use any longer [9]. They work with two molds on the blow-side forming, which are loaded alternately. This approach is advantageous in terms of longer reheat and more homogeneous glass thickness distribution but is much more complicated, expensive, and prone to jamming.

In a narrow sense, IS-machines consist of a gob-distributor and delivery equipment, blank-side forming, invert, blow-side forming, and take-out and have several identical sections aligned in a row (Figure 1). The only differences between sections are the individual delivery (as different distances from gob-cut to mold need to be overcome) and the distance of the section to the annealing lehr. The differences in delivery distances cause different gob speeds and different gob arrival-times at loading and thus require different section-timings. The differences in distance to the annealing lehr may cause different containers temperatures at the hot-end coating and at lehr entrance. When entering the lehr, there is, for example, a difference of 50 K or more in surface temperature between containers from section 1 and from section 12, which are the farthest from the annealing zone.

The IS-machines in principle can be adapted to all three forming processes that have been mentioned earlier. To a certain extent the machines can be converted between a triple-gob setup to a quad-gob setup or, given another machine construction, from a triple-gob setup into a double-gob setup. How widely a machine can be adapted depends on different parameters, especially on the inner-section distance, which describes the possible center distances of the molds to each other within one section. The type of setup to be used depends on different parameters such as the size and weight of the container to be produced, desired machine speed, and portfolio of the respective glass-manufacturing plant.

5.2 The IS-Machine Families

The IS-machines can be separated into three groups:

- 1) Pneumatic-controlled IS-machines with angular mold-opening.
- 2) Pneumatic-controlled IS-machines with parallel mold-opening.
- 3) Servo-electric-controlled IS-machines with parallel mold-opening.

In the earliest types of IS-machines, all movements are controlled by pneumatic valves. The mold opening and closing is in an angular motion, which means that in a multi-gob setup at the blank-mold-side, the inner blanks are more widely opened than the outer blanks, causing difference in radiation between the glass and the open

blanks. At the blow-side, the inner molds are not opened as wide as the outer molds, which may lead to difficulties in machine accuracy and forming.

A significant step forward, therefore, was the introduction of pneumatic-controlled IS-machines with parallel mold-opening and closing. Here the mold-halves from the inner, middle, and outer cavity open in a parallel motion to each other. This leads to more comparable conditions between the molds of a given section. Furthermore, the parallel closing and opening is more precise, leading to a more reliable forming. In the color section of this Encyclopedia, a picture of a modern pneumatic-controlled IS-machine is shown.

The next logical improvement was to exchange the pneumatic-controlled movement for a servo-electric-controlled motion to take advantage of the enhanced stability, reliability, and precision of servo-electric drives. In this way, motions are much more easily cushioned and are gentler for the hinges, molds, and also for the glass itself. In the latest generation of IS-machines, mold opening and closing, plunger motion, invert, blow-head, take-out, pusher, and other parts are thus servo controlled.

The machine speed is a general parameter to describe the production performance for a given container. It is expressed as the cavity rate (C), namely the number of containers produced per minute (cpm) for each cavity considering the total numbers of cavities (N_S) of the IS-machine:

$$C = \frac{\text{cpm}}{N_S} \quad (5)$$

For a 12-section machine with a triple-gob setup and container output of 324 containers per minute, the cavity rate C is, for instance, $324/12 \times 3 = 9$. Hence, a 12-section IS-machine with a triple-gob setup producing 240 containers per minute is running a lower cavity rate than a 10-section IS-machine with the same triple-gob setup producing the same number of containers per minute. Highly efficient IS-machines can go up to cavity rates of 25 for small container sizes. This rate translates to production speeds of more than 700 containers per minute. In general, one can state that the higher the gob weight and the larger the container size, the lower is the corresponding cavity rate.

As illustrated in Figure 8 for 0.3-l beverage bottles, the performance of IS forming machines has steadily improved since their inception in the 1920s. In 90 years, one forming line has been producing 26 times more containers per minute. And in the same period the weight of such containers could be decreased from more than 300 to less than 170 g. These figures show vividly the very strong potential that this forming process had when it was invented.

Figure 8 Performance increase of IS forming machines over the years in containers per minute.

5.3 Delivery Equipment

The delivery equipment consists of the gob-distributor (also called scoop), the trough, and the deflector. After the gob has been cut, it falls into the scoop which distributes the gobs to the different sections in the forming machine. The gobs slide through the respective troughs and then are redirected by the deflectors into the blank-molds. Although the delivery section looks like a simple part of the IS-machine, it bears considerable neuralgic points. The gob temperature decreases during the delivery but the upward side of the gob loses less heat than the side in contact with the metal delivery, which in some cases is in addition cooled and lubricated. Forming problems can thus happen if the gob acquires a non-uniform temperature profile.

The speed of the gob when it leaves the deflector is also an important parameter. When leaving the deflector, the gob is loaded into the mold. The higher the speed of the gob, the more beneficial it is for a good loading. Too slow a gob speed may lead to incorrect loading and hence to problems in the forming process or defects in the final container. In extreme cases, the gob is not fully loaded into the mold and the upper end of the gob is caught by the baffle. This leads to immediate failure of the respective section. The average gob speed at loading is between 6.5 and 7.5 m/s.

5.4 Blank-Side Forming

At the blank-side the three different forming processes come to play as explained in Section 3. Molds at the blank-side are usually made of laminar cast-iron. The glass gob is loaded into these molds and is formed into the parison. Because of process-sequence, the parison is formed upside down, the finish facing downward and

the bottom of the container upward before the invert leads to the proper upright formed final container. Upon forming of the parison, the mold is always cooled by air to allow fast heat extraction from the glass. As already explained, this is necessary to have a stable parison with a high enough viscosity after the mold has opened. If the parison is too hot and hence has a too low viscosity, it may collapse after opening the mold, causing section failure.

Different mold-cooling techniques are available. Most dominant are inside-mold cooling systems, where air is lead through channels in the mold either from below or from above and an older technique called stack-cooling. Here, fins are attached to the outside of the mold and the mold is streamed by air. This version is less efficient than inside mold cooling so that it usually leads to lower machine speeds.

5.5 Invert and Reheat

After forming of the parison, the blank-mold opens and the parison is transferred via an invert to the blow-side. The invert consists of an invert-arm in which the finish equipment with neck-ring and guide-ring is fixed. As soon as the blank-mold opens and invert takes place, the so-called reheat starts. During the blank-side process, the glass-surface has been cooled down, especially through the contact with the molds and blowing air. The glass viscosity rises in this way, which is necessary to give the parison a certain rigidity to move it without deformation. After having been released from the blank-mold, the outer parts of the parison get reheated from the hotter inner part through thermal conduction, which is in fact needed to lower again surface viscosity before the last forming step that will give the container its final shape.

5.6 Blow-Mold Forming

The forming of the final container in the blow-mold is from a mechanical point of view identical for all three forming processes (BB, PB, and NNPB) as explained in Section 3.

As with parison forming at the blank-side, final blowing at the blow-side can also be aided by vacuum. A main task for the blow-mold is to extract as much heat from the container as fast as possible to increase its viscosity, stabilize its shape, and avoid deformations during take-out and transport of the container after it has been released from the blow-molds. Because of this need to extract large amounts of heat in a short time, blow-molds often are made out of aluminum-bronze, which has much higher heat conductivity than cast-iron, hence allowing faster heat removal from the container.

A picture of a triple-gob setup in the color-section of this Encyclopedia shows the parisons just having arrived at the blow-side and the final containers just having been removed from the blow-mold and placed over the dead-plate by the take-out.

6 Hot-End Handling, Hot-End Coating, and Annealing

The conveyor belt transports the container to the annealing lehr for stress-relaxation. Once the container has left the IS-machine, a first inspection often takes place with cameras that record the infrared images of the hot containers. From these images, defects can be identified and immediate corrections of the process can be initiated. This is very beneficial as the feedback between defects and applied corrections is direct and without the time delay that would occur if the container were first annealed and then inspected.

Before entering the annealing lehr, the outside body (not the finish) of the containers receives a hot-end coating of a 5–15 nm thickness. Even so thin, the hot-end coating serves different important functions. It first saturates the highly reactive surface bonds that are present at the surface of the new glass container. It also provides a surface suitable for good adhesion of the cold-end coating, which is applied later. Furthermore, it may slightly increase the strength of the container by disabling surface flaws that have been introduced during the forming process.

As precursor for hot-end coating most frequently used is monobutyltin-trichloride, $C_4H_9SnCl_3$ (MBTC) or tin-tetrachloride, which both gives rise to a SnO_2 coating on the container. The process is chemical vapor deposition under air at atmospheric pressure (atmospheric CVD) and is supported by the moisture of the air. The reactions that take place are:

Other precursors based on titanium or titanium-silicium are also in development to yield a TiO_2 or TiO_2 - SiO_2 coating. As explained, after forming and hot-end transport, the containers from different sections experience different cooling whereas the surfaces of a given container cool faster than its bulk, the rate being higher for the outer than for the inner surface. These differences create tensile stresses in

the container, which can lead to spontaneous breakage. Containers are thus reheated in the glass transition range in a continuous-annealing lehr long enough to ensure complete stress relaxation. The annealing times depend on the size of the containers, but are typically between 45 and 60 minutes. The containers can then cool down to room temperature homogeneously.

7 Cold-End Handling and Inspection

When they leave the annealing lehr, containers have a temperature between 80 and 120°C. They are coated a second time in a spray process. The main purpose of this cold-end coating is to protect the container against scratches upon further handling and later at the filling line. Usually a polyethylene wax is used to decrease surface friction, hence making the containers less susceptible to scratches when being handled or touching one another. The cold-end coating also serves to provide a surface suitable for good adhesion of the label, which is usually fixed at the filler.

After application of the cold-end coating, another inspection takes place in a highly automated way such that additional inspection by human eye is applied only in rare cases. Most inspection systems are based on various sophisticated optical systems, each checking for a certain type or group of potential defects that include flaws, scratches, cracks, blisters, seeds, loose or stuck glass particles, or dimensional errors of the container. Because special attention is paid to the finish of the container, mechanical inspection systems are, for instance, applied for testing that it is free of obstacles. Finally, random checks are made offline, e.g. to check that the strength exceeds definite values that depend on the kind of container. For impact strength, usually a minimum lot-size of 30 containers is tested on a shift, daily or some other regular basis, depending on the container made and plant procedures. The container is hit by a pendulum of a certain weight – depending on the chosen specification and domain of the container – in a well-defined matter until it breaks. As for the burst pressure strength, which is especially relevant for carbonated liquids such as sparkling wine, water, and champagne, the container is filled with water and its pressure is increased until breakage. Also here, due to the Weibull-characteristics of brittle materials, a minimum of at least 30 containers should be tested. After inspection, the containers are pelletized, wrapped, and prepared for shipment.

8 Perspectives

With the introduction of PET and other plastic containers, the glass industry has experienced a severe loss in market share for certain types of products such as juice, water, and milk. After years now the market seems balanced and the container-glass industry could maintain a quite stable production level of ca. 65 million tons worldwide, which amounts to ca. 200 billion containers in 2012.

Recently, however, disadvantages of plastic containers have been recognized. Because of the leaching of endocrine-active substances, phthalates and other substances into the container content [10, 11] and the dispersion of plastic waste on land and especially in the oceans [12], glass might even be able to gain more acceptance from the consumer. Here, glass can play out its strengths as, among other positive aspects, it is fully inert and can be 100% recycled. Furthermore, glass in a landfill does not pose any threat to the environment as it degrades to the components it was made of.

Nevertheless, glass has also its well-known drawbacks and a positive future of container glass strongly depends on the capabilities to overcome them. First, there is the fact that glass containers are energy-intensive to produce. Emission control, CO₂-trading, rising energy costs, and other environmental regulation force the glass-industry to push limits farther (Chapter 9.7). As processes are already highly optimized, there are no more “low-hanging fruits.” Although the effort that has to be made financially and risk-wise increases exponentially with the possible benefit that can be gained, the container-glass industry is aware of the need of innovations. The increasing number of batch and cullet preheaters or the latest concepts to

allow heat recovery for oxy-fuel fired furnaces illustrate the kind of efforts made to keep shifting the limits.

Other weak points are the fact that glass containers are brittle and mostly regarded as heavy. In specific instances, however, weight is considered a positive aspect of glass packaging. For example, think of the smooth texture, the reassuring heft, and the feel of value when lifting a glass bottle of wine or perfume. Nevertheless, many investigations have been carried out to decrease the weight of glass containers while increasing their strength. Coatings based on silica-sol-gels (Chapter 8.2) can, for instance, increase the strength of glass containers by 20% or more.

Besides, most impressive are current developments which aim at thermal strengthening of containers. After forming, the containers are reheated and then cooled from both inside and outside much faster and in a much more controlled way than in an annealing lehr. In this manner, compressive stresses at the inner and outer surface are introduced, which significantly increase the strength of the glass so that containers can be lightweighted further or be reused. The key to this development is to control the cooling very precisely and to adjust the balance between compressive stresses at the surface and tensile stresses in the bulk of the container (Chapters 3.7 and 3.12).

Innovations are also targeted in the field of glass-contact materials. Coatings for enabling a full non-swabbing production of all types of containers are investigated, but this task is still unsolved. Furthermore, it is highly desirable to avoid all lubricants that are currently used in shear-, trough-, and mold-lubrication. This would allow a full “dry-gob” delivery that would give considerable advantages over current process.

Figure 10 Parison just before blow-mold closing and final container on the blow-mold-side. Source: Courtesy Bucher Emhart Glass.

Concerning the IS-machine itself (Figures 9 and 10), a significant improvement would be to ensure a more precise and controlled forming process and, hence, a more homogeneous wall-thickness distribution in the final container. This could, for instance, be achieved by a direct gob-loading without the need of a delivery or by a forming process, which would allow a more precise reheat to have a more homogeneous final container forming. Because cost competition with alternative packaging is one of the biggest drivers and deciders for innovations, however, all the aforementioned approaches and concepts will have to distinguish themselves not only by their technical feasibility but also by their economic efficiency.

Continuous Glass Fibers for Reinforcement

Hong Li and James C. Watson

Fiber Glass Science and Technology, PPG Industries, Inc., Shelby, NC, USA

1 Introduction

Numerous examples of the use of glass drawn as fibers can be found throughout history. The early Egyptians wrapped glass fibers over clay vessels and then fused them to form glass vessels. Venetian glass blowers in the sixteenth and seventeenth centuries used glass fibers to decorate elaborate glass articles. Glass fibers were even used as fabric elements in fashion garments in the late nineteenth century. It was in the mid-1930s, however, that two key developments created the means for glass fibers to become the base for a new industry based on composites—organic polymers reinforced with glass fibers, more commonly known as glass reinforced plastics, or GRP. The first was improvements in the process of manufacturing glass fibers at the Owens-Illinois Glass Company so that commercial fibers could be made in a multifilament strand form that met basic material handling requirements for downstream processing into composite structures [1]. The second was the development of polymeric resin systems by DuPont and others that could be combined readily with glass fibers. These glass-fiber reinforced polymer–matrix composites offered key material advantages over conventional metallic materials, including light weight, stiffness, and strength, and resistance to corrosion and fatigue.

Today, glass fibers have become the most widely used and cost-effective reinforcing fibers in the arena of commercial polymer–matrix composites. Early melt spun processes producing discontinuous fibers have evolved to today's large-scale direct melt continuous fiber-forming operations. One of the first needs for continuous fibers was for insulation of electrical wires for high-temperature applications, leading to the development

of a new glass composition based on a $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-B}_2\text{O}_3$ system that met the electrical requirements and subsequently became known as E-glass. Because these fibers also exhibited excellent mechanical properties and could be made in relatively high-volume manufacturing operations, the original E-glass compositions rapidly spread into many composite applications. Today, the glass fiber reinforcement spectrum has grown to include an increasing array of specialty glass compositions that are targeted for key expanding markets in electronics, transportation, corrosion, construction, and in energy management.

Prior to 2000, most major glass fibers manufacturers were concentrated in North America and Western Europe. Today, fiberglass production facilities are flourishing in China and beginning to spread to other regions of the world to satisfy a constantly growing demand of GRP. It is the intent of this overview to provide insight into the technology that is associated with the continuing success of glass as a reinforcing fiber. Fiberglass technology associated with both material characteristics and manufacturing processes are described at a high level.

2 Commercial Glass Fibers

2.1 History of Fiberglass Development and Glass Chemistry

2.1.1 Fiber Types

Reinforcement glass fibers can be broadly divided into two categories – general-purpose and premium special-purpose fibers. The former are known as E-glass and subject to specific compositional ranges as defined by recognized standards such as ASTM D578 [2]. Historically, E-glass fibers have been predominant in the commercial production of fiberglass products for use as

Reviewers: R. Conradt, RWTH University of Aachen, Aachen, Germany
J. Thomason, The University of Strathclyde, Glasgow, Scotland, UK

reinforcements in various industrial polymer–matrix composites applications. Other types of fibers that have been used in special purpose and low-volume applications include S-glass, R-glass, D-glass, ultrapure silica fibers, and hollow fibers [3].

Continuous glass fibers for composite reinforcement have been categorized by the specific properties required for end-use applications (Figure 1). An overview of the historical timeline of the development and commercial use of these major glass types is represented on the horizontal axis. Further detail on the typical oxides and oxide ranges, physical and mechanical properties, and processing-related properties that are characteristic of the major glass types used in glass fibers are listed in Tables 1 and 2, respectively. More specific examples of recent developments in the areas of D-, S-, and R-glasses are also included.

2.1.2 E-Glass

First commercialized in the late 1930s [1], E-glass fiber remains the most widely used class of fiberglass for GRP materials [3, 4]. Its composition primarily lies within the ternary $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system with B_2O_3 and F_2 contents that vary from 0 to 10 wt % and 0 to 2 wt %, respectively. For much of its history, E-glass fiber production incorporated B_2O_3 in commercial compositions at levels of 7–8 wt %, which provided an optimal balance of melting and fiber-forming characteristics, mechanical properties, and electrical properties. Over time, however, increasingly restrictive environmental emissions requirements for particulates have been driving costs up for emission control systems. Countries such as Canada and Norway were leaders in the push to improve environmental conditions, leading to the introduction of the first boron-free commercial glass fibers. These glasses had in addition excellent corrosion resistance under strongly acidic conditions [7]. They have been designated as E-corrosion resistant (E-CR) glass fibers in the late

1970s. Over time, optimizations of minor oxide components such as TiO_2 , ZnO , and MgO served to improve their cost and manufacturing efficiencies while also providing proprietary regions in the compositional space as their use was growing rapidly.

In key areas outside of the corrosion markets, however, there was resistance to move to low-boron compositions. The electronics industry, dominated by E-glass fabrics used in printed wiring boards (PWB), relied on the unique value set of electrical consistency, dimensional stability, processing predictability, and low cost provided by conventional E-glass over many years and resisted any change in the E-glass standards. The aerospace industry also resisted the change, based on a well-defined history of performance of conventional E-glass and a desire to minimize any risk, however small, which might be incurred by what was perceived as a significant material change.

As a consequence of these developments, commercial E-glass fibers today fall into two major categories: low or zero B_2O_3 levels for general reinforcements, and higher B_2O_3 levels (>5%) for electronic and aerospace applications. The distinction between these categories is clearly defined in ASTM D578 [2].

2.1.3 C-Glass

Other reinforcement fibers containing B_2O_3 were developed in the early 1940s as C-glass, which has limited use as discontinuous fiber products for roofing materials. Continuous boron-free variants of C-glass fibers with improved chemical resistance to acids came to market in the mid-1960s. The composition is primarily composed of Na_2O , CaO , Al_2O_3 , and SiO_2 . The absence of boron resulted in improved acid resistance; the mechanical performance (strength and modulus) of C-glass fiber is inferior to those of both E-glass and E-CR glass, however, so that applications of this glass in the reinforcements industry have been limited to nonstructural uses

Figure 1 History of commercial continuous fiberglass development (most active period in development shown and beyond 2015 most intensive research areas projected are S, R, and D glass fibers) and standard nomenclature/classification based on their key properties used in commercial applications [4].

^a C-Glass (China) is specified by Chinese Standard JC583-1995.

^b A-glass fiber (close to window glass composition) has low hydrolytic resistance, sensitive to moisture attack at room temperature, and, hence, is inappropriate for GRP composite applications.

^c ZrO₂ in AR-glass is specified by ASTM C1666/C1666M-08.

such as nonwoven fabrics for corrosion liners, building insulation materials, sewage pipes, etc. For many years, C-glass served as the primary form of glass fiber for low-cost regions of the world in emerging markets, at present less than 10% in volume relative to E-glass fibers produced each year in China. The balance of mineral components with no need for a boron source provided a glass fiber based on widely available raw materials that could be easily manufactured in low-technology operations. Hence, these properties led to the broad commercialization of C-glass as a low-cost substitute for E-glass fibers in regions where modern fiberglass furnace technology was not commonly available. Many early fiber producers in China used C-glass. The trend today, however, is to move away from C-glass fibers to the production of E-glass and other high-performance fibers. Little development has occurred since the mid-1980s, and C-glass fibers represent less than 5% of fibers used in glass fiber reinforced composites today.

2.1.4 AR-Glass

As named for its alkali-resistant properties, AR-glass fiber was invented in the mid-1960s and first commercialized by Pilkington Brothers in the United Kingdom in the early 1970s under the trade name Cem-Fil®. It was presented as a glass fiber option for reinforcing concrete structures. The glass chemistry was actually developed by a chemist at the Building Research Establishment and licensed to

Pilkington by the National Research and Development Corporation, leading to its initial commercial application. The glass chemistry is primarily comprised of Na₂O, CaO, ZrO₂, and SiO₂ with a small amount of Al₂O₃. The higher Al₂O₃ found in most commercial glass fibers results in lower ZrO₂ solubility. Unlike E-CR fibers, AR-glass fiber offers high resistance to alkaline corrosion as well as to acid corrosion. This resistance is attributed to the formation of a protective layer rich in ZrO₂ on the fiber surface in corrosive media. Because of the relatively high Na₂O and low Al₂O₃ levels, the fiber modulus and tensile strength are lower than for E-glass fibers despite the high concentration of ZrO₂. The overall higher production and material cost of AR-glass limits its utility to challenging fiber applications in cement reinforcement. Current developments are focused on increasing ZrO₂ solubility to improve further corrosion resistance and to improve melting and fiber-forming costs.

2.1.5 D-Glass

An optimum combination of dielectric constant (D_k) and dissipation factor (D_f) over a frequency range of 1 MHz to 40 GHz is provided by pure SiO₂ glass. This property set is of particular utility in the field of PWB and electronic chips and circuitry, driven by the dramatic growth of computers and consumer electronics. It is to allow production of glass fibers approaching the performance of SiO₂ glass in a reasonable commercial process that

Table 2 Typical properties of fiberglass found in literature and/or commercial market [3, 4, 6, 7].

Note: CTE values correspond to temperature range from room temperature to 300 °C; T_{soft} corresponds to glass viscosity of 10^{7.6} Pa·s as typically used in fiber glass production; T_F is defined by melt viscosity of 10² Pa·s as a reference temperature for drawing fibers; T_M is defined by melt viscosity of 10 Pa·s as a reference fining temperature to be reached in the industrial melting process.

D-glass has been designed. The earliest D-glass fiber composition was essentially a binary mixture of SiO_2 and B_2O_3 . Although D-glass fiber has significantly lower processing temperatures than pure SiO_2 , these temperatures are still substantially higher than those of E-glass fibers for PWB yarns. Melting temperatures are greater than 1600°C and fiber drawing temperatures greater than 1400°C . Recent developments have widened the D-glass fiber composition space by introducing Al_2O_3 , alkaline earth oxides (MgO , CaO , BaO , and SrO), and/or small amounts of Li_2O (Table 1) [5]. These composition modifications significantly lowered glass melting and fiber drawing temperatures, providing more favorable production costs and improved commercial viability. The drawback is a modest increase in D_k and D_f relative to the original D-glass composition. To achieve target product electrical properties, PWB laminators can use different resins with lower D_k and D_f . It is also possible to change the PWB layer stack and layout to meet target electrical performance for high-end PWB substrates. Another development is to lower the coefficient of thermal expansion of the glass fiber to improve PWB substrate thermal stability. This reduces thermal fatigue susceptibility and leads to a reduction in thermally induced cracking on chips. Continuing improvements in D-glass compositions keeps glass fiber at the forefront as a key element of choice in smaller, faster, lighter, and more electrically dense electronic components.

2.1.6 S-Glass

Known as S-glass, fibers primarily composed of MgO , Al_2O_3 , and SiO_2 were first developed in the late 1960s for high-temperature and high-strength applications and further expanded into military ballistic protection applications in the 1970s [6]. Because of high liquidus temperature (1470°C), fibers must be drawn at temperatures significantly greater than 1500°C to avoid fiber breakage caused by crystallization as the fibers are formed. This property attribute means that S-glass fibers must be drawn in a much lower viscosity range than that of typical commercial fibers (Section 3.2). The challenges of this severe process limit the number of product forms and result in very high costs that have limited the commercial utility of S-glass fibers to high-performance markets such as aerospace and military applications where strength and weight combined can justify a premium over other materials. There are no large-scale commercial production platforms in the S-glass family. Derivatives of S-glass have been investigated through introduction of small amounts of B_2O_3 and other oxides (Li_2O , CeO_2) to improve glass melting and fiber-forming performance. To date no large commercial-scale production has materialized.

2.1.7 R-Glass

For military applications, R-glass was first developed in the mid-1960s within the quaternary $\text{SiO}_2\text{--Al}_2\text{O}_3\text{--CaO--MgO}$ system. In its original chemistry, its production, like that of S-glass, was limited because of the requirements imposed by its high melting temperature. The addition of CaO to the S-glass ternary system improved the processing conditions required to make glass fibers while still providing a high level of strength, but conditions were still more challenging than E-glass. Developments centered around the R-glass compositional range increased in the mid-00s, driven by the needs of wind-turbine blade producers who required longer blades with higher-modulus glass fibers to reduce the unit cost of electricity generation. Most of the improved technology made is based on reducing glass melting temperature while increasing fiber modulus, which has been realized by optimization of mixed alkaline earth oxides (MgO/CaO). As a result, large-scale furnaces and large direct-draw bushing operations are possible. [4]. These developments have provided a balance of mechanical performance, cost, and large-volume production capability that is in good alignment with the scale of production and cost of energy drivers in the wind-energy composites market. The speed at which these new high modulus fibers have been put on the market is unprecedented in glass-fiber history.

2.1.8 Glass Type Summary

With its derivatives such as ECR glass, E-glass continues to dominate global commercial sales of glass fibers for reinforcement applications. The unique combination of mechanical properties, weight savings, and durability combined with a wide array of available form factors in the form of fiber diameter, strand size, resin compatibility as delivered by sizing chemistry, continuous or chopped forms, and cost-effectiveness make E-glass fibers by far the best value for designing and manufacturing high-performance composites on a large scale. In parallel with ongoing improvements in E-glass performance, technology developments associated with high-performance fibers, i.e. re-engineered or derivatives of S-glass, R-glass, and D-glass will continue to be key focus areas in the future. These technologies serve to expand the growth of glass-fiber reinforcements in transportation, aerospace, both traditional and renewable energy, and safety and security markets. These added technology options in glass fiber address light weight, high strength and high modulus [4, 6], improved durability, and improved electrical performance such as low signal loss and high-speed communication in the PWB industry [5].

In developing new glass fibers, a fundamental understanding of glass network structures and glass properties

for both performance and processing are critical. In boron-containing glasses such as E- and D-glass, speciation of boron in the network, i.e. $\text{BO}_4 \leftrightarrow \text{BO}_3 + \text{NBO}$ (non-bridging oxygen), is affected by both melting temperature and glass composition [8]; in turn, melt viscosity and glass dielectric property are affected. Besides the speciation of silicate network affected by modifying oxides [9], all commercial silicate glass fibers contain alkaline earth oxides and alumina; an in-depth understanding of composition effect (particularly high field strength metal oxides, MO_x) on speciation of aluminum, i.e. $\text{MO}_x + \text{AlO}_y \leftrightarrow \text{MO}_{x-1} + \text{AlO}_{y+1}$ ($x = 7, 8$ and $y = 4, 5, 6$) [9–11], can assist in glass design for achieving better glass mechanical properties and facilitating melting and fiber-forming processes.

2.2 Major Fiberglass Producers

Worldwide production of E-glass fibers reached about 7.3 million metric tons ($7.3 \cdot 10^{12}$ kg) in 2018 and is projected to grow continuously. The expansion of E-glass fiber production capacity is expected to occur in parallel. Fiberglass companies can be ranked by total annual sales in volume whereas total production capacity of each company is much more difficult to find in the public domain. The current top 10 fiberglass producers globally based on sales in past 5 years are listed in Table 3. The largest rate of expansion has taken place in China, where newly built furnaces in recent years ranged from annual capacity of 30 000 metric tons to 120 000 metric tons per furnace.

3 Manufacturing of Glass Fibers

3.1 Primary and Secondary Processes

The production of glass fibers encompasses a wide range of processes, from raw-material sourcing, batch weighing and mixing, batch-to-glass melting and fining, fiber drawing with the application of a water-based organic sizing, to finally drying. Much of today's glass-fiber production for reinforcements incorporates direct processing wherein the finished product, whether wound into a continuous spool of fiberglass strand or chopped directly after the fibers are formed and coated with sizing, is produced in one step as a part of the forming operation. Secondary downstream processes are still in use for some applications and may include twisted yarn on bobbins, roving packages made by assembling collections of smaller strands into larger strands, fibrous mats made from chopped or continuous strands bound together by mechanical or chemical binders, and chopped products for some specialty applications. The general process is sketched in Figure 2. For E-glass fiber production, combustion technology is moving from natural gas–air or oil–air to natural gas–oxygen to achieve better energy transmission efficiency. Where C-glass fiber is still in production, the use of syngas remains prevalent for furnace and combustion systems because of lower capital costs. For both types of fibers, electric boost technology has increased in utilization for energy efficiency and for lowering top firing and hence lowering the crown temperature of the furnace to prolong its life. The following sections briefly discuss some of the key areas of glass melting/fining, fiber drawing, and sizing chemistry design.

Table 3 Top 10 fiberglass producers (2008 – 2013).

Name	Headquarter	Sales ranking	Major market	History

3.2 Glass Melting and Fining

Commonly used raw materials for E-glass fiber include sand (SiO_2) as the primary silicon source, kaolin or china clay consisting of kaolinite ($\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$) as the primary source of aluminum, limestone (CaCO_3) or quicklime (burnt lime, CaO) as that calcium, and boric acid (H_3BO_3) as that of boron. More complex minerals are often used in place of or in combination with these major components to manage cost, improve melting performance, or utilize locally sourced ingredients. Some examples of commonly used complex minerals include pyrophyllite ($\text{Al}_2\text{Si}_4\text{O}_{10}(\text{OH})_2$), colemanite ($\text{Ca}_2\text{B}_6\text{O}_8(\text{OH})_6 \cdot 2\text{H}_2\text{O}$), ulexite ($\text{NaCaB}_5\text{O}_6(\text{OH})_6 \cdot 5\text{H}_2\text{O}$), borax ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 8\text{H}_2\text{O}$), fluor spar (CaF_2), dolomite [$\text{Mg, Ca}(\text{CO}_3)_2$], spodumene ($\text{LiAl}(\text{SiO}_3)_2$), and soda ash (Na_2CO_3). For C-glass fiber, albite ($\text{NaAlSi}_3\text{O}_8$) is commonly used to reduce the need for soda ash. For simplicity, primary phases of the above natural raw materials are used; all of them can contain other mineral phases and/or impurities, for example, iron from ore and grinding process.

Batch reaction chemistry and kinetics in glass melting have been widely studied with various experimental techniques, including differential thermal analysis (DTA), differential scanning calorimetry (DSC), X-ray diffraction, electrical resistance and temperature distributions from molten glass to the batch pile, for laboratory batch sizes from as little as 0.1 g up to 10 kg in mass [12–14]. Models have also been developed from a thermodynamic approach [15].

As illustrated in Figure 3, the batch-to-melt conversion process of representative E-glass and ECR-glass batches can be characterized in the following steps:

- i) De-hydroxylation of batch ingredients, i.e. removal of both moisture water (120–150 °C) and crystalline

water in the minerals, (colemanite, 350–450 °C; kaolinite or pyrophyllite, 500–600 °C).

- ii) Decarbonization, i.e. removal of carbonates (limestone, 700–800 °C).
- iii) Formation of intermediate crystalline phases (~1000 °C).
- iv) Liquid phase formation (1000–1400 °C).
- v) Final dissolution of residual phases (sand, 1250 °C) [12].

The majority of the batch reactions are endothermic, the energy consumption of these steps constituting a significant portion of the total energy spent in the glass melting process. Finally, the glass fining step, which varies as a function of furnace throughput, consumes even more energy. The fiberglass industry is continuously searching for new raw materials to lower the energy consumption in batch melting [12] and improved technology to increase the furnace throughput without sacrificing glass quality. This in turn reduces the unit energy consumption of glass melted and glass fiber produced. In practical terms, successful implementation of these approaches can provide savings of up to 20% compared to typical E-glass melting energy demands of 7000–8000 kJ/kg of glass [12].

One generally carries out glass melting and fining by controlling the melt temperature of the furnace hot spot near or higher than T_M at which the melt viscosity is 10 Pa·s (Figure 4), which will ensure sufficient fluidity of the molten glass to promote both mixing of the batch components and removal of seeds (or bubbles). The latter is also aided by the use of fining agents such as sodium sulfate (Na_2SO_4), which is commonly used in making E-glass fibers. However, because much higher melting temperatures are often required for specialty glass fibers, other fining agents such as manganese dioxide (MnO_2) or cerium dioxide (CeO_2) are also used with or without

Figure 3 Differential scanning calorimetry output of E-glass batches with and without boron from room temperature to 1400 °C (10 K/min heating rate), illustrating both endothermic and exothermic reaction events as batches are converted into glass through initial steps of dehydration and decarbonation. The intermediate silicates formed are anorthite ($\text{CaAl}_2\text{Si}_2\text{O}_8$) and/or wollastonite (CaSiO_3). Source: PPG, 2014.

added sodium sulfate. Fining agents may also serve as oxidizing agents to control the iron oxidation states for both glass melting and fiber drawing process as will be discussed in more detail in a later section.

Fining action from the decomposition of Na_2SO_4 dissolved in the melt is created as the molten glass stream moves toward the higher temperature fining zone, or hot spot, of the furnace. The melt with dissolved sulfate becomes oversaturated at higher temperatures ($>1350^\circ\text{C}$) and sulfate decomposition and bubble formation begins to occur. The onset temperature of sulfate decomposition depends on many factors – water vapor pressure in the furnace combustion space, water dissolved in the glass, organic species in the batch materials, any addition of carbon to the batch, partial pressure of oxygen above the melt, and others [16]. Driven by buoyancy action, bubbles containing SO_2 and O_2 travel to the melt surface; along the way the sulfate bubbles expand, stripping smaller bubbles of CO_2 (primarily from decomposition of carbonates) and air (primarily N_2) trapped in the melt. The sulfate fining process can be described by the reaction

where O^{2-} is the free oxygen, which depends on glass composition. With other fining agents, for example CeO_2 , oxygen fining gas is generated according to the reaction

Adequate use of fining agents is critical. The quantity needs to be optimized based on the furnace firing setup, types of fuel and air or oxygen used, glass composition,

and types of fiber products to be made. Excessive use of fining agents can result in uncontrolled melt foaming. The foam layer reduces energy transfer from the combustion space to the glass melt beneath the foam blanket, resulting in energy waste because of excessive firing required to maintain the underglass temperature and in poor glass quality caused by inhomogeneous melting. Excessive foam can also lead to potential overheating of the furnace crown, shortening the furnace service life.

3.3 Fiber Forming

The *bushing* is the device that controls the fiber-drawing process. It is the interface between the glass melting and fiber formation processes. Bushings are made of precious metal alloys of platinum (Pt) and rhodium (Rh), typically in alloys of 90Pt/10Rh or 80Pt/20Rh. The tip plate of the bushing contains an appropriate number of tips or nozzles, typically ranging in number from 100 up to 8000 and in diameter from 0.75 to 2.00 mm. Proper selection of these parameters then enables production of the desired number and diameter of glass fiber filaments in a strand of fiberglass (Figure 2b). The bushing is electrically heated to provide very precise control of the temperature and, thus, of the viscosity of the glass flowing through the nozzle. The combination of tip size and glass viscosity coupled with the controlled speed of the take up winder allows for very good control of finished-product filament diameters and linear-strand density.

The rate of melt flow (F) through the bushing nozzle or bushing tip follows Poiseuille's relationship, i.e. flow is proportional to $r^4 h / l \eta$ where r is the fiber radius, h is the depth of molten glass above the bushing tip plate, l is the length of nozzle, and η is the melt viscosity at the tip plate [3]. In practice, the actual interior geometry of

the nozzle may be varied, which affects the melt flow rate for a given winder speed; modified Poiseuille equations can be found in the literature [3].

The fiber attenuation process is usually completed in less than a second, during which the diameter of the melt stream through the tip changes by three orders of magnitude from millimeters at the tip to micrometers in the finished filament. At a fiber attenuation speed between $3 \cdot 10^4$ and $3 \cdot 10^5$ m/s, depending on bushing type and specified fiber product, the estimated fiber cooling rate is approximately $0.5 \cdot 10^6$ K/s for a typical commercial fiber-forming process. Stable drawing processes require adequate control of the fiber cooling rate, which is managed through a combination of process controls, including appropriate bushing design, cooling manifolds (commonly known as fin coolers), cooling air flow, and water spray. In addition, one optimizes the fiber drawing and cooling rates by tuning the oxidation state of iron (either from raw material impurities or intentionally added) in the glass, specifically the concentration of ferrous ion (Fe^{2+}).

The oxidation–reduction of iron in the melt is affected by glass chemistry and oxygen partial pressure ([16, 17], Chapter 5.6)

and by the presence of other multivalent species either from additives or impurities,

In general, drawing processes for making finer or smaller diameter fibers (and typically smaller bushings also) require glasses with a relatively lower concentration of Fe^{2+} (hence, slower cooling rate) than coarse fibers made from larger bushings (hence, higher cooling rate). The control of the iron oxidation state (or ferrous ion concentration in glass) is directly related to the amount of fining agent in the batch and the total iron in the batch, both of which are adjustable variables to maintain process stability. The ferrous ion concentration in glass is routinely monitored in production with a colorimetric method through acid digestion of a glass powder sample or with a calibrated UV-VIS spectroscopic method on an optically polished glass disk.

In commercial production, glass fibers are drawn at a temperature T_F where melt viscosity is near 100 Pa·s (Figure 4). Stable melt viscosity at the tip plate is critical for an efficient fiber-forming process. If melt viscosity at the tip plate is too low (i.e. too high temperature at the tip plate), spreading of the glass melt across multiple tips on the tip plate results in flooding and disruption. If melt

viscosity is too high (i.e. too low temperature at the tip plate), fiber drawing tension increases and the stable forming cone at the tip exit begins to fail, causing fiber breakage [3]. In addition, the actual forming temperature must be greater than the glass liquidus temperature, T_{liq} , by at least 50 °C to reduce the risk of devitrification. Microcrystals formed in colder spots along a primary canal or forehearth (Figure 2a), no matter how small, can lead to significant fiber breakage in the drawing process and hence, adversely impact productivity.

In making commercial glass fiber products for reinforcements, various processes are used to provide the desired end form. Direct draw or single end winding, direct chopped fibers, and numerous downstream secondary processes may be employed. Depending on the product needs, the types of bushings vary in dimension, number of tips, and tip diameters. In addition to the glass and process elements necessary to produce commercial glass fibers, the surface of the fiber must be treated to provide optimum compatibility of the inorganic glass fiber with the organic resins used in the reinforcements industry. This leads naturally into a discussion on the role of sizing chemistry.

3.4 The Role of Sizing/Binder in Glass Fiber Products

The long history of growth in both volume and breadth of glass-fiber commercial successes has been driven by unique combinations of strength, stiffness, weight, and cost attributes that can be achieved through glass chemistry. However, to realize fully the value of the glass fiber in a reinforced composite, a means must be provided to facilitate the effective interactions between the inorganic fiber and the organic polymer that together make up a reinforced composite material. One maximizes this interaction by designing an interface that synergistically combines the material properties of each element. A design that provides for effective load transfer between the constituents transforms an inherently heterogeneous material into one that behaves as a homogeneous structure.

In fiber-glass composites, the system that delivers the optimum interfacial properties is the *sizing* or binder that is applied to the surface of the fiberglass. The sizing is generally applied as a continuous coating just after the fibers are formed and before the individual glass filaments are gathered into a strand below the bushing. The most common sizing formulations comprise a water-based mixture of molecular species such as adhesion promoters, film formers, lubricants, and other processing aids as summarized in Table 4. It is the role of the sizing chemist, working in conjunction with the glass scientists and the process engineers, to deliver a sizing formulation that appropriately enables efficient production rates of the

Table 4 Classification and functionality of ingredients in fiber sizing/binder formulations.

Classification	Functionality
Coupling agents	Adhesion promoters that bond or couple the glass surface with specific matrix resin systems; may also provide excellent filament protection and increased dry breaking strength.
Film formers	Hold filaments together and provide protection to the fiberglass strand.
Film modifiers	Modify the film formation to increase strength, flexibility, and tackiness.
External lubricants	Provide resistance to abrasion damage at external contact points such as strand guides in downstream processes.
Internal lubricants	Reduce the filament-to-filament abrasion within the fiberglass strand.
Emulsifiers/ Surfactants	Form stable suspensions or emulsions of immiscible ingredients, generally in water-based systems.
Other process aids	May be used as required to control foam, wetting, static behavior, biological activity, and any other special requirements by a particular end-use or internal processing need.

fiberglass while also providing maximum compatibility with the targeted composite polymer matrix and the end-use performance requirements.

Good sizing design begins with a selection of the appropriate adhesion promoter that will provide good bonding between the inorganic glass surface and the reactive sites in the targeted polymer system. The most widely used class of chemicals for this function are organosilanes. These species can be designed to promote reaction between the silanol sites on the glass surface and on the organosilane molecule, leading to an Si–O–Si bond at the glass/polymer interface. The silanes as supplied are hydrolyzed in the final sizing formulation to provide Si–OH groups that can then condense with the Si–OH groups on the glass surface to provide strong interfacial bonds. The organic functionality of the silane is then chosen to maximize compatibility with the target polymer in the final composite. Common examples are shown in Table 5. Other classes of chemicals that have seen more limited utility as adhesion promoters include organotitanates and organo-chromium complexes.

It is important to note that characterization of the quality of the sizing as well as the glass fiber in the finished composite is critical to confirming technical success of a fiberglass product. Good adhesion at the interface implies the formation of an interphase that makes the materials compatible through covalent bonding, and provides a discrete pathway for stress transfer between the materials. Many standardized tests related to interfacial adhesion, interfacial shear stress, tensile stress, modulus, and hydrolytic stability have been developed over the years and are widely available in international standard testing organizations such as ASTM and ISO. Many academic laboratories have also developed more sophisticated tests. One example is the measurement of composite critical fiber length [18]. As defined by Eq. (5), the critical fiber length (l_c) is the minimum fiber

length at which fibers with given diameter d reach their ultimate tensile strength σ_{fu} and the matrix/fiber interface experiences a maximum interfacial shear stress τ_y , [18]. When $l > l_c$, an increase in interfacial adhesion will result in a decrease in critical fiber length and may lead to improvements in other properties such as impact strength in certain resin systems. However, the sizing may also act to protect the fiber from surface damage and defects in addition to providing improved adhesion. In that case, reduction of fiber surface damage would lead to an increase in the critical fiber length by increasing σ_{fu} . Interestingly enough when $l > l_c$ and the composite is stressed to failure, then the fiber will break at regular intervals of l_c within the composite. This result can be used to estimate the interfacial shear stress:

$$l_c = \frac{\sigma_{fu}}{2\tau_y} d \quad (5)$$

This example also serves to illustrate that broader conclusions from micromechanical experiments should consider that different outcomes may result depending upon material selection. The most common material options include chopped or short fibers vs. continuous fibers and thermoset vs. thermoplastic resin systems, which of course complicates the task of the sizing chemist in product development.

It remains for the sizing chemist to complete the establishment of the final formulation from a virtually limitless palette of film formers, process aids, and modifiers to deliver the desired performance of the fiberglass as a commercial product. Commercially, the resultant amount of sizing on the fiberglass surface is typically in the range of 0.3–1.5 wt % of the dry fiberglass.

An excellent in-depth review of the complexity of this field from the sizing chemists' point of view can be found in Thomason's book, *Glass Fibre Sizings: A Review of the Scientific Literature* [19].

Table 5 Common organosilanes.

Chemical name	Structure	Class
γ -Aminopropyl trialkoxy silane	$(\text{RO})_3\text{Si}-(\text{CH}_2)_3-\text{NH}_2$	Amine
γ -Methacryloxypropyl trialkoxy silane	$(\text{RO})_3\text{Si}-(\text{CH}_2)_3-\text{OOC}(\text{CH}_3)\text{C}=\text{CH}_2$	Methacryl
γ -Glycidyloxypropyl trialkoxy silane	$(\text{RO})_3\text{Si}-(\text{CH}_2)_3-\text{O}-\text{CH}_2\text{CHCH}_2\text{O}$	Epoxy
Vinyl trialkoxy silane	$(\text{RO})_3\text{Si}-\text{CH}=\text{CH}_2$	Vinyl
R = CH_3CH_2- or CH_3-		

4 Markets and Applications

4.1 Global Glass Fiber Reinforced Polymeric Composite Markets

The glass fiber reinforced polymeric composites market will grow from about \$18 000 million in 2010 to an estimated \$30 000 million in annual shipment value by 2017 according to a recent survey. These composites find many applications in commercial markets globally. A breakdown by major regions of the world is shown in Figure 5 for the Americas, EMEA (Europe, Middle East, and Africa), and Asia Pacific.

Construction and transportation dominate the Americas market place for GRP composites, with construction taking the largest share. Other segments are more or less equally distributed among industrial, oil and gas, and wind-turbine blade applications, along with numerous smaller segments. In the EMEA region, construction and transportation are also the largest markets, but here the leading industry is transportation. The wind-turbine blade segment is much higher in Europe, and the other segments hold similar shares as seen in America. In the Asia Pacific region, once again transportation and construction combined are the largest segments. In this region, however, electronics and industrial markets are more prominent, combined with a large “other” segment driven by the large variety of needs and applications in the region. The electronic segment is particularly strong, reflecting the strong position of the PWB industry and its supply chain of E-glass fiber, fabric, and laminators in the Asia Pacific region.

Generally, GRP composite materials are classified into two categories: thermoplastic and thermoset. Thermoplastic GRP products most commonly use resins based on polypropylene, polyamides (nylon 6 and 6,6), polyesters (polybutylene terephthalate, polyethylene terephthalate), and many other specialized thermoplastic polymers. Thermoset GRP products commonly use resins based on epoxies, unsaturated polyesters, and vinyl esters, with smaller but growing applications use phenolic and urethane-based resin systems as well as other

specialty resins. Thermoplastic resins generally exhibit higher ductility and impact resistance, while thermoset resins offer better strength and modulus and higher thermal stability. There are many new developments underway in both processing and resin chemistry that often blur the traditional divisions between thermoplastic and thermoset-based glass fiber composites. The glass fiber industry will continue to be at the forefront in supplying reinforcement solutions for these new developments.

Thermoplastic automotive applications include window frames, automobile body components, dashboard sections, and bumper beams. Typical processes for combining fiber forms with thermoplastics resins as intermediates for molding of final parts include extrusion compounding of short fibers, glass-mat thermoplastic sheet, and long-fiber thermoplastic compounding.

Major thermoset products include composite pipes for oil and gas, marine, and industrial applications; wind-turbine blades; flue-gas desulfurization tanks and towers; PWB; boats; construction beams and structures; composite leaf springs; and numerous sporting-goods applications. Other components are countless and limited only by the imagination. Typical conversion processes for thermoset composites include filament winding, pultrusion, resin transfer molding, hand lay-up, spray deposition, continuous laminating, centrifugal molding, sheet molding compounds, and bulk molding compounds.

Glass fibers can also be used as a reinforcement for cement structures, in many cases with AR-glass fibers as already noted. Like E-glass, it also finds utility in some of these applications where short-term strength is the major requirement. Some geotextile reinforcements also use E-glass as a base in a coarse mesh form. Chopped glass fibers are the predominant reinforcement for asphalt roofing shingles, primarily in North American markets (*Source: fiber glass market study, PPG, 2014*).

4.2 Emerging GRP Composite Markets

Traditional E-glass still dominates total glass fiber volume produced around the world, with a well-established

Figure 5 Global GRP composite market shares in America, EMEA, and Asia Pacific regions. Source: Fiber glass market study, PPG, 2014.

history of delivering value in many markets for more than 70 years. This trend is expected to continue because of the E-glass value in use and the maturity of the manufacturing technology. Along with its variants, E-glass will continue to be the material of choice in most applications. Fiber manufacturers will continue to move toward more environmentally compliant variants, and product development scientists will continue to tailor the glass composition, form factor, and surface chemistry to maximize synergy with developing resin chemistries and process technologies. A good example of this evolution is E-CR glass and its performance in strongly acidic environments. This adequacy has resulted in the specification of E-CR glass as a requirement in applications such as waste water pipe systems, desulfurization towers in power plants, and filtration bags in power plant or cement productions (Figure 6a).

Specialized fibers, including redesigned and more manufacturing friendly versions of S-glass, R-glass,

and D-glass for high-strength, high-modulus, and premium electrical properties, respectively, continue to be in demand where limits are being pushed to the extreme for traditional E-glass. Some examples include aerospace, driven by weight and fuel economies; wind energy, driven by the need for increased stiffness at a fair value cost in order to achieve lower energy costs; transportation, driven by fuel economy and energy management in crashes; better electrical properties, driven by increased bandwidth, faster computing speeds, and miniaturization; and energy storage, driven by higher strength for hydrogen storage tanks and other components. A specific example of the role of improved glass design is related to the design of ultra-long wind-turbine blade. Newly designed high modulus and low-density glass fibers will likely replace E-glass fibers (Figure 6b) in the future, helping to drive the unit cost of electricity generation to a more competitive level.

Figure 6 Improvement in fiber properties through compositional changes. (a) Effects of boron reduction on acid stress corrosion performance as shown by a comparison of boron-free ECR and E-glass fibers [7]. (b) Improvement of composite unidirectional tensile modulus with newly designed R-glass fibers for various potential applications for both thermoplastic and thermoset composites [4] (σ_{app} – applied tensile stress on rod samples, σ_{UTS} – ultimate tensile strength of as-received rod samples, unidirectional nonwoven fabric reinforcement – UD composite panel, long fiber thermoplastics – LFT).

5 Perspectives

It is expected that E-glass and its variants will continue to be the predominant form of glass fiber for most reinforcements markets in the near term. However, as larger volume applications grow with increased performance needs, the glass fiber industry will face challenges to develop manufacturing technology platforms capable of making these products at costs acceptable to the markets. Innovation is needed in both glass chemistry and manufacturing technology to grow specialty fiber businesses that usually provide higher profitability than traditional glass fiber

markets. Some examples of manufacturing technologies could include new melting furnace designs, new melting techniques, new fining methods for higher temperatures, and new refractory materials for high-temperature operations. In terms of fiber-glass chemistry, an in-depth fundamental understanding of glass structure–property relationships will aid glass optimization for performance and manufacturing scalability. Most ongoing research, including molecular dynamic modeling, focuses on local structure of both network work formers (primarily Si, B, and conditionally Al) and network modifiers (primarily alkali, alkaline earth, and rare earth).

1.7

Simulation in Glass Processes

Patrick J. Prescott and Bruno Purnode

Owens Corning Science & Technology Center, Granville, OH, USA

1 Introduction

Numerical simulations of glass processes are performed in lieu of physical trials, which often involve conditions too harsh to allow measurements, are difficult to control, or are prohibitively expensive. Used as a screening tool, a simulation model can thus allow technologists to avoid several iterations of actual physical trials on an industrial apparatus. Alternatively, simulations can be used to examine phenomena which are too difficult to observe in practice because of the extreme environment of glassmaking. Moreover, numerical simulation allows for fundamental phenomena to be studied, thanks to its capability of identifying and controlling factors that influence the process. Such factors cannot usually be independently modified in the real process, in view of its complexity, and the insights gained from such virtual experiments can be used to guide technology development efforts.

Following the advent of electronic computers in the mid-twentieth century, these methods were pioneered in the 1960s to deal with glassmaking problems elementary enough to be handled with the simplifying assumptions required by the then limited computing power. Much more complex and realistic 3-D problems can of course be tackled now as massive increase in this computing power has dramatically changed engineering analysis in general. Concomitant with hardware advances have been significant developments in software, including both computational algorithms and user interfaces. Several commercial offerings of the relevant software are available for glassmaking. Process engineers are encouraged to utilize such tools. Some of these software packages are general purpose, adaptable to a wide range of situations,

whereas others serve the glass-processing industry specifically.

Both general-purpose and niche-software products will be used in the example simulations presented in this chapter where the focus will be put on the mathematical techniques used to simulate the two major phenomena involved in glassmaking, namely fluid flow and heat transfer. Mathematical models, formulated from the classical laws of physics, are used to calculate relevant field variables, such as temperature, velocity, stress, etc., within a glass manufacturing process. Modeling results are then interpreted with post-processing procedures, which are less abstract than ever before, thanks to modern techniques capable of displaying results in a geometrical context. When applied to fluid flow and heat transfer, these techniques are collectively referred to as *computational fluid dynamics* (CFD).

To review these new methods, we will first summarize the main six steps they successively involve from the definition of the problem of interest to its solution. The various physical phenomena relevant and their mathematical description and computational treatment will then be expounded. Subsequently, a few representative examples of model simulation will be presented to demonstrate the capabilities and the value of modeling to a glass manufacturing enterprise. Finally, a brief section on the importance of managing simulation data will be provided.

2 A Brief Overview

Numerical simulation is a process made up of the six steps summarized in Table 1. These are: (1) identify the objectives of the modeling study, (2) construct a geometrical domain and discretization of the system of interest (i.e. meshing or grid generation), (3) build the simulation

Step	Process	Description
1	Objective	Identify needed results – quantitative summaries – qualitative insights – comparisons.
2	Geometry and mesh	Construct CAD model and discretize into elements or cells.
3	Physical conditions	Assign materials and properties to regions, boundary conditions, sources, and other abstractions to account for physical behavior. (Can affect Step 2)
4	Solve	Select solver options, such as under-relaxation coefficients, gradient estimation methods, convergence criteria, etc., and solve. (Can affect Step 2 or 3)
5	Post-process	Review computed results, prepare contour plots, vector plots, flow pathlines, and other computed values from results.
6	Document and archive	Prepare presentation or report and store all information in appropriate database.

model by selecting physical phenomena and applying various physical data (e.g. material properties, boundary conditions), (4) choose numerical parameters to execute the calculations and effect a solution, (5) post-process the simulation results, and (6) document them and archive the modeling data. Each of these is important, and some are mutually dependent on one another.

The first step of identifying the objective cannot be overemphasized. It will drive the rest of the process and will lead to key assumptions to be applied along the way. The complexity of the model or its level of detail can very much depend on its purpose. Thus, the second step of geometrically defining the computational domain and discretizing it very much relies on the modeling objectives and requires good judgment in order to resolve the details of interest without adding human and computational effort that are not key to the objectives sought. Therefore, it is crucial to determine a good balance between model accuracy and the effort needed to reach a solution.

Generating a mesh is often the main bottleneck in the modeling process, as it is often rendered difficult by geometrical details which have a negligible effect on the results of interest. Meshing software with de-featuring options may be helpful, but good guidance at the outset of the modeling project is very valuable. This point is well illustrated in Figure 1a where are sketched two ways to represent a burner block used in a hearth (i.e. the heated canal lined with refractory material separating the melting furnace from the forming machinery). The geometry shown in Figure 1a more accurately represents the actual shape of the burner block, but it yields highly skewed and undesirable mesh cells. The low-quality mesh is the result of three surfaces, one of which is curved, intersecting at a point, which will either cause divergence of the computational algorithm or lead to spurious results. Extreme grid refinement thus is required to achieve acceptable mesh quality. An alternative that alleviates the meshing problem, without having a significant effect on computed results, is shown in Figure 1b.

Sound engineering judgment is also needed to build the simulation model, the third step of the simulation process. Many decisions are required. For example, can symmetry be assumed? Another example is linked to the steadiness of the process and whether an assumption of steady state is justified or if transient conditions must be considered. Treating fundamental properties like viscosity (Chapter 4.1) and thermal conductivity (Chapter 4.5) as constant or temperature-dependent represents another decision that must be made by the numerical analyst. Sometimes, it is advantageous to use constant properties to establish an initial solution, followed by another solution attempt with variable properties. This strategy has been used effectively where the initial constant property solution serves as the initial estimate for the more accurate, variable property simulation. It is recommended to begin a simulation project erring on the side of simplicity, and then to add complexity in subsequent simulations.

It is also the case that the physical modeling decisions will affect the geometrical and meshing procedures. For example, a perforated plate through which a fluid flows could require extremely detailed meshing (Figure 2); or the effects of the hole pattern could be accounted for with a much less refined mesh using a more abstract method, in which the screen is characterized by a permeability which relates velocity and pressure drop. The decision on how to proceed will depend on the objectives of the study.

Post-processing (Step 5) is also very important, as it requires the analyst to execute good judgment on the results obtained. Before extracting information and insights from the results, the analyst must scrutinize the calculated field variables, as well as checking for balanced conservation laws; that is, checking for sufficient numerical convergence must be performed. Finally, management of simulation data (i.e. electronic model files) should not be overlooked since it determines the efficiency with which the simulation process is executed.

 (b) slight modification with improved mesh quality.

**Figure 2** Example of a screen with small-scale features requiring a high mesh density to be resolved.

3 Fundamental Phenomena, Governing Equations, and Simulation Tools

3.1 Glass as a Continuum

The basic principles of engineering science are applied in CFD simulations. These involve fluid mechanics and usually various other phenomena that are typically considered to fall within the category of thermal sciences. A brief overview is provided, but for complete development, interested readers not yet familiar with the details are referred to various textbooks (e.g. [1–3]). Physical

phenomena specific to glass processes must be accounted for within the framework of three fundamental principles and will be reviewed later with respect to a few chosen examples. Readers are also directed to a volume edited by Krause and Loch [4] for a collection of excellent examples of numerical simulations applied to glass processes.

Forming the foundation on which CFD models are constructed, the fundamental principles of classical physics account for conservation of mass, momentum, and energy. Conservation of momentum follows from Newton's three laws of motion, whereas energy conservation is of course the first law of thermodynamics. Contrary to what is done for the very small systems simulated in theoretical studies (Chapters 2.8 and 2.9), it is impractical to account for the motion or energy level of each individual atom or structural entity at the scale relevant to industrial processes. Instead, it is recognized that, for length scales of engineering practicality, substances can be characterized with intensive properties (i.e. per unit volume or mass). Because it describes the mass per unit volume of a particular substance, density is a simple example of such a property that is independent of the size of the system. This abstraction allows substances to be treated as a *continuum* and allows for powerful mathematical models to be constructed.

3.2 Transport by Advection and Diffusion

Referring again to well-recognized texts [1, 2], we will remind that the principle of conservation of mass, applied to an infinitesimally small control volume (CV), is mathematically expressed as

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \vec{V}) = 0, \quad (1)$$

where ρ is the density and $\vec{V}$ is the velocity vector. Equation (1) is often called the continuity equation. A mathematical expression of the conservation of momentum is

$$\frac{\partial (\rho \vec{V})}{\partial t} + \nabla \cdot (\rho \vec{V} \vec{V}) = \nabla \cdot (\vec{\sigma}) + \vec{B}, \quad (2)$$

whose left-hand side represents the time rate of change of momentum (i.e. mass times acceleration), and the right the forces acting upon the fluid by adjacent fluid particles (i.e. the divergence of the stress tensor, $\vec{\sigma}$) and other relevant objects through gravity or electromagnetically generated forces (i.e. a net body force per unit volume, $\vec{B}$). Forces attributable to adjacent fluid particles are collectively represented by *stress*, which is another intensive property quantifying force per unit area.

An important requirement for mathematical modeling of fluid flows is to relate internal fluid stresses to characteristics of the fluid's motion. Such a relationship, which depends on the substance, is termed a *constitutive relationship*. There are many types of material behavior, requiring different constitutive models, but the most commonly used model relates shear stresses to strain rate (i.e. velocity gradient) in a linear manner. Fluids to which this linear relationship applies are known as Newtonian fluids. For example, a shear stress component τ_{xy} for a Newtonian fluid is characterized with

$$\tau_{xy} = \mu \frac{\partial u}{\partial y}, \quad (3)$$

where μ is the dynamic viscosity and u is the x -direction component of the velocity vector. For a Newtonian fluid, viscosity is independent of the strain rate. As long as it is homogeneous, glass is a Newtonian fluid although its viscosity is a very strong function of both composition and temperature (Chapter 4.1).

When the Newtonian constitutive model is substituted into the more general momentum Eq. (2) and the fluid is assumed to be incompressible, the result is the well-known Navier–Stokes equation

$$\frac{\partial (\rho \vec{V})}{\partial t} + \nabla \cdot (\rho \vec{V} \vec{V}) = \nabla \cdot (\mu \nabla \vec{V}) - \nabla P + \vec{B}, \quad (4)$$

where P is the fluid pressure. Not all fluids behave according to Eq. (3). Such non-Newtonian fluids must be mathematically modeled with different constitutive relations substituted into Eq. (2) [5, 6].

Note that Eq. (4) is a vector equation, although it can be decomposed into vector component (scalar) equations, which is often done for the numerical application. In

Cartesian coordinates, these component (scalar) equations are the following:

$$\frac{\partial (\rho u)}{\partial t} + \nabla \cdot (\rho \vec{V} u) = \nabla \cdot (\mu \nabla u) - \frac{\partial P}{\partial x} + B_x, \quad (5)$$

$$\frac{\partial (\rho v)}{\partial t} + \nabla \cdot (\rho \vec{V} v) = \nabla \cdot (\mu \nabla v) - \frac{\partial P}{\partial y} + B_y, \quad (6)$$

$$\frac{\partial (\rho w)}{\partial t} + \nabla \cdot (\rho \vec{V} w) = \nabla \cdot (\mu \nabla w) - \frac{\partial P}{\partial z} + B_z. \quad (7)$$

In fluid mechanics problems, the unknown field variables are the three components of velocity (e.g. u , v , and w) and fluid pressure, requiring four independent equations, which are the three momentum component Eqs. (5)–(7) and the continuity Eq. (1).

The equation for energy conservation is derived in a similar fashion. A common form of the energy equation is

$$\frac{\partial (\rho C_p T)}{\partial t} + \nabla \cdot (\rho C_p \vec{V} T) = \nabla \cdot (k_t \nabla T) + S_T, \quad (8)$$

where C_p and T are the specific heat and temperature, respectively, and k_t the thermal conductivity. In Eq. (8), the transient and advective transport terms are on the left side, whereas the right side has the conduction term and all other energy transfers accounted for as “sources.” An example of a “source” is Joule dissipation; that is, electrical energy converted to thermal energy by an electrical current passing through a resistive material (with an associated drop in electric potential).

In CFD, various transport phenomena are cast in the following general form known as the advection–diffusion equation [7],

$$\frac{\partial (\rho \phi)}{\partial t} + \nabla \cdot (\rho \vec{V} \phi) = \nabla \cdot (\Gamma \nabla \phi) + S_\phi, \quad (9)$$

where ϕ represents a generic field variable related to the property of interest, and Γ a generic diffusion coefficient. For example, temperature is the relevant field variable in the energy Eq. (8). (Likewise, ρC_p is substituted for ρ in the energy equation as it represents its “thermal inertia” per unit volume.) The first member on the left side of Eq. (9) is a transient term, which can be ignored for steady-state problems. The second is the advection term, representing transport by fluid motion. The first member on the right side of Eq. (9) is the diffusion term, representing transport by atomic-scale interactions, and all others are treated as “sources,” often because the model contains mathematical expressions which do not admit to the form of the one of the three standard terms.

Several commonly used mathematical expressions for the advective–diffusive transport of various field variables

Table 2 List of commonly used transport equations in advection–diffusion form.

		ϕ	Transient	+	Advection	=	Diffusion	+	Source
A	Continuity	1	$\frac{\partial \rho}{\partial t}$	+	$\nabla \cdot \left(\rho \vec{V}\right)$	=		+	0
B	Momentum (x -direction)	u	$\frac{\partial(\rho u)}{\partial t}$	+	$\nabla \cdot \left(\rho \vec{V} u\right)$	=	$\nabla \cdot (\mu \nabla u)$	+	$-\frac{\partial P}{\partial x} + B_x$
	Momentum (y -direction)	v	$\frac{\partial(\rho v)}{\partial t}$	+	$\nabla \cdot \left(\rho \vec{V} v\right)$	=	$\nabla \cdot (\mu \nabla v)$	+	$-\frac{\partial P}{\partial y} + B_y$
	Momentum (z -direction)	w	$\frac{\partial(\rho w)}{\partial t}$	+	$\nabla \cdot \left(\rho \vec{V} w\right)$	=	$\nabla \cdot (\mu \nabla w)$	+	$-\frac{\partial P}{\partial z} + B_z$
C	Energy	T	$\frac{\partial(\rho C_p T)}{\partial t}$	+	$\nabla \cdot \left(\rho C_p \vec{V} T\right)$	=	$\nabla \cdot (k \nabla T)$	+	S_T
D	Turbulent kinetic energy	k	$\frac{\partial(\rho k)}{\partial t}$	+	$\nabla \cdot \left(\rho \vec{V} k\right)$	=	$\nabla \cdot (\mu_{t,k} \nabla k)$	+	S_k
E	Turbulence dissipation	ε	$\frac{\partial(\rho \varepsilon)}{\partial t}$	+	$\nabla \cdot \left(\rho \vec{V} \varepsilon\right)$	=	$\nabla \cdot (\mu_{t,\varepsilon} \nabla \varepsilon)$	+	S_ε
F	Electric charge/potential	E		+	0	=	$\nabla \cdot (k_e \nabla E)$	+	0
G	Species A	mf_A	$\frac{\partial(\rho mf_A)}{\partial t}$	+	$\nabla \cdot \left(\rho \vec{V} mf_A\right)$	=	$\nabla \cdot (D \nabla mf_A)$	+	S_A

are listed in Table 2. Some are expressions of a fundamental principle, while others are consequences of further abstraction (e.g. turbulent kinetic energy), although still derived from first principles.

In Table 2, the rows D and E show the components of turbulence quantities for turbulent kinetic energy, k , and turbulence dissipation rate, ε . Glass flows are never turbulent, thanks to the stabilizing influence of glass extreme viscosity, in contrast to flows of air, gas, oxygen, combustion fumes, and other fluids that are part of glass processes.

3.3 Turbulence

Turbulence represents an unstable flow condition that is naturally unsteady. Nevertheless, turbulent flows are commonly treated as steady because the velocity field can be well described with time-averaged values, and similarly for other field variables such as temperature. That is, for any given location, a field variable can be decomposed into a time-invariant average, plus a fluctuating component. The time and length scales associated with turbulent fluctuations are small compared with the important features of a glass process, but the effects of these fluctuating quantities are profound and must accounted for in simulation models.

There are many model formulations to account for turbulence, most having variations tuned for specific flow conditions. It is beyond the scope of this chapter to review even a few of them. The so-called k – ε model is the most

prolific, which is why its two equations are mentioned in Table 2. The source terms S_k and S_ε are related to the rate of strain of the average flow.

$$S_k = \mu_t S^2 - \rho \varepsilon \quad (10)$$

and

$$S_\varepsilon = C_{1,\varepsilon} \mu_t \frac{\varepsilon}{k} S^2 - C_{2,\varepsilon} \rho \frac{\varepsilon^2}{k}, \quad (11)$$

where $C_{1,\varepsilon}$ and $C_{2,\varepsilon}$ are model constants, and S represents the modulus of the strain rate tensor determined from the time-averaged velocity field. (The rate of strain tensor is defined as $\dot{E} = \frac{1}{2} \left[\nabla \vec{V} + (\nabla \vec{V})^T \right]$.) Sometimes, these

sources are embellished with additional terms to account for effects such as buoyancy or compressibility.

The purpose of a turbulence model is to account for transport occurring through the turbulent eddies that are not explicitly resolved in the simulation. Such transport occurs through advection as represented by the second term on the left side of the generic transport Eq. (9), averaged over time for steady-state problems. As mentioned above, these eddies are smaller than typical features of interest, but they are much larger than the molecular scale associated with diffusion through the first term on the right side of Eq. (9). The k – ε model accounts for turbulent transport by treating it as a diffusive phenomenon characterized by a “turbulent viscosity,” μ_t ,

$$\mu_t = \rho C_\mu \frac{k^2}{\varepsilon}, \quad (12)$$

where C_μ is another model constant, which adds up to the Newtonian viscosity to yield an effective viscosity, μ_{eff}

$$\mu_{\text{eff}} = \mu + \mu_t. \quad (13)$$

It is usually the case that $\mu_t \gg \mu$ and $\mu_{\text{eff}} \approx \mu_t$. Likewise, similar substitutions are made for the diffusion coefficients of other transport equations.

3.4 Radiative Heat Transfer

Heat transfer by conduction and convection is accounted for by Eq. (8) (or C in Table 2), which is also compatible with radiative heat transfer applied as a boundary condition on an opaque surface. However, glass and other media (e.g. combustion gases) are commonly semitransparent in glass processes, that is, they emit, absorb, and scatter IR radiation volumetrically.

Radiative heat transfer significantly differs from transport by advection and diffusion so that it cannot be mathematically described by an equation of the form of Eq. (9). It is instead governed by an integrodifferential equation, known as the radiative transfer equation (RTE) [3],

$$\begin{aligned} \frac{dI(\vec{r}, \vec{s})}{ds} + (\alpha + \alpha_s)I(\vec{r}, \vec{s}) &= \frac{\alpha n^2}{\pi} \sigma T^4 \\ + \frac{\alpha_s}{4\pi} \int_0^{4\pi} I(\vec{r}, \vec{s}') \Phi(\vec{s}, \vec{s}') d\Omega, \end{aligned} \quad (14)$$

where $I(\vec{r}, \vec{s})$ represents the radiation intensity at a position $\vec{r}$ and in the beam direction $\vec{s}$; α and α_s are absorption and scattering coefficients, respectively; n is the index of refraction; $\Phi(\vec{s}, \vec{s}')$ the scattering phase function quantifying the portion of incident radiation from any direction $\vec{s}'$ redirected into direction $\vec{s}$; and $d\Omega$ is a differential solid angle. The absorption coefficient and index of refraction are material properties, whereas the scattering coefficient and phase function Φ depend on physical conditions (e.g. size of soot particles), as well as on material characteristics. Note that Eq. (14) reduces to a first-order differential equation when scattering is not considered.

As for the first term on the left side of Eq. (14), it represents the change in beam intensity per unit length in beam direction $\vec{s}$, whereas the second accounts for the decrease in beam intensity caused by the combined actions of absorption and scattering. While absorption has the effect of increasing local temperature, scattering only redirects a portion of the beam without absorbing energy. Finally, on the right side of Eq. (14), the first term accounts for emission, which tends to lower local

temperatures, and the last term for scattering of IR from all directions into the beam path $\vec{s}$.

Radiation is a directional phenomenon and is in addition spectral in nature in that its intensity in principle depends on the wavelength of the IR beam. When spectral variations can be assumed to have negligible effects, Eq. (14) is written for a medium that is said to be *gray*. Extending the RTE to include spectral effects is straightforward [3], but not presented here.

Note that, Eq. (14) only accounts for IR intensity without determining directly temperatures within a material. Integrated over all directions, however, the net effects of absorption and emission are added to the source term S_T in the energy Eq. (8), thereby affecting local temperatures. There are several methods to account for the directional nature of the RTE. Referring to texts on radiation heat transfer for the details of their derivation [3], we will discuss some of them in Section 4.

3.5 Discretization Methods, Solution Algorithms, and Model Specifications

3.5.1 Finite Element and Control Volume Formulations

Several kinds of computational algorithms exist to solve for the field variable in Eq. (9). One category is known as the finite element method (FEM), where the field variable is assumed to have a functional form or shape over discrete portions of the problem domain. In finite element, the governing equations are multiplied by a weight function and then integrated over an element. The weight function can have various forms. As an example, with the Galerkin method, the weight function is the shape function itself. Another category is known as the CV method, where the problem domain is divided instead into a multitude of small volume elements, each characterized by a single, representative value for each relevant field variable. The conservation laws and fluxes are enforced on each CV, where transport or exchange across adjoining boundaries are determined with finite-difference estimates (usually, a truncated Taylor Series expansion based on unknown or estimated adjacent CV values) of the various derivatives in the governing equation. Whereas both of these numerical methods involve discretizing the problem domain into a multitude of elements or volumes that appear to be virtually the same, they are different as explained in detail in [7, 8]. Generally, more mathematics are involved with the FEM whereas the CV method, dealing with fluxes, can easily be associated with representations giving a physical significance to the problem.

3.5.2 Physical and Numerical Specifications

Once geometrical definition and meshing are done, simulation models are set up with various input

specifications (i.e. Steps 3 and 4 in Table 1). Those associated with Step 3 are physical; that is, they describe the physical characteristics of the process, which in turn affect the degree to which field variables at neighboring grid cells (or mesh nodes) influence each other. Essential are material specifications and associated properties, such as viscosity (for fluids), thermal conductivity, density, specific heat, etc. Many software products have material properties defined for commonly used materials, which must be complemented for materials of interest not dealt with in the existing material database. Various boundary conditions such as flow rates, temperatures, and other state parameters at all flow inlets are other physical specifications to be included along with wall boundaries conditions, which could be, for example, a prescribed temperature, heat flux, or temperature-dependent heat flux.

Every portion of the boundary of the simulation domain requires a boundary condition for each transport equation considered. These conditions can be in the form of a prescribed field variable (e.g. temperature T), prescribed flux by definition proportional to the gradient of the field variable (e.g. $q'' = -k_t \frac{\partial T}{\partial n}$), or a mixed condition where the flux depends on the field variable (e.g. $q'' = h(T - T_c)$). Software products generally provide default values for many of these but, for best practice, much care is recommended to review and verify each boundary condition specification with a checklist. Experience has shown that unintended specifications can be the root cause of the frustrating experience of trying to resolve inconsistencies between simulation results and measured data and/or expectations.

In Table 1, model set up specifications for Step 4 are related to the numerical methodologies employed to render a solution. Examples include so-called under-relaxation coefficients (URCs), which are used to stabilize the evolution of iterative calculation procedures required to solve nonlinear problems. These coefficients are very important since many factors cause virtually all glass-process simulations to be nonlinear.

URCs have values between 0 and 1, where 1 represents no under-relaxation and 0 does not allow the estimated field variable to change from one iteration to the next. In general, larger URC values thus allow for more rapid convergence, but divergence will occur instead if a URC is too high. Conversely, small values of URCs tend to be more robust but require many more iterations to satisfy convergence criteria. It remains a bit of an art to specify URCs, especially because optimal values can very much depend on other numerical specifications.

Additional specifications can include the manner in which advection terms are discretized, whether velocity components are solved consecutively as scalar

components or coupled to one another, along with pressure, or if energy and radiation equations are solved in a coupled or uncoupled manner. Choosing these options can depend on the capabilities of the computer used as algorithms that couple equations require larger amounts of memory.

As just noted, prescribing numerical parameters is an art so that experience is required for an analyst to become efficient and develop realistic expectations. Nevertheless, many commercial software providers offer recommended or default values to begin a simulation. Most numerical parameters will not affect the converged solution, but only the time required to obtain the solution. However, some numerical schemes will provide more accurate results for a given mesh than others although their differences should become imperceptible with sufficient grid refinement. For example, a second-order upwind differencing scheme for advection terms will produce less “false diffusion” than a first-order upwind scheme [7].

4 Simulations in Glass Manufacturing Processes: A Few Examples

4.1 Fundamental Studies

As already stated, the importance of a particular phenomenon can be explored by numerical simulations in such a way that the mathematical treatment and/or its numerical implementation can be examined to assess the best way to account for the physical effects of interest. A good example of this approach was the early one-dimensional study of Glicksman [9] of various physical effects on fiber formation. He formulated his model by manipulating the conservation equations (A)–(C) in Table 2, where glass velocity, filament diameter, and temperature were assumed to vary only in the axial direction of the fiber draw. This relatively simple model was very helpful in understanding the relative roles of glass viscosity and surface tension on fiber-forming dynamics, as well as the influences of radiative and convective cooling.

As computational resources grew, more sophisticated models were developed to explore further fiber-forming dynamics from 2-D axisymmetric models with free surface boundary conditions [10, 11]. Both steady-state and transient simulations were performed and revealed the onset of unstable forming conditions, which could lead to poor product quality and/or reduced process efficiency. A view of the deformed finite element mesh, representing fiber attenuation as it is drawn, is shown in Figure 3, whereas the excellent agreement found between numerical and experimental results of the fiber attenuation (Figure 4) illustrated the reliability of the method.

Figure 3 Deformed finite element mesh during a simulation of the drawing of a glass fiber. Source: *International Congress on Glass* [10].

Figure 4 Fiber radius attenuation: comparison of numerical and experimental results for an extension ratio of 19 000. Source: *International Congress on Glass* [10].

Another study examined the manner in which radiation within a semitransparent glass is considered [12, 13]. It was performed in the context of a simplified glass furnace geometry. Because radiative energy is both absorbed and emitted volumetrically, this study examined two methods for accounting the radiative transport with equations (A)–(C) in Table 2. One method is the computationally convenient Rosseland approximation [3], in which one accounts for radiative transport by appropriately adjusting the thermal conductivity of glass; the other employs

the discrete ordinates method (DOM) [3] to solve independently the radiative-transport Eq. (14), the results of which are then coupled to the energy Eq. (8) through source terms. The DOM requires significantly more computational effort and, thus, longer run times. For large models with millions of mesh cells/elements, the difference in run times can be significantly important. For many problems in glass processing, the Rosseland approximation will yield sufficiently accurate results but some situations require a more detailed accounting of the radiative transport. For example, if the refractory-wall temperatures are of interest to assess wear rates, then a DOM might be a better choice. Also, in forming operations, length scales associated with the forming apparatus may be significantly smaller than those for which the Rosseland approximation is valid. A modeling simulation aimed at assessing such fundamental matters is sometimes an appropriate ancillary simulation to perform. Both methods were investigated and compared in [12].

4.2 Glass Melting Furnace

4.2.1 Models

Relatively small simulation models provide a means to understand the behavior of an isolated part or function of a glass process, or to assess numerical treatments. However, many problems require the mutual interactions of several parts or processes to be considered simultaneously. A good example is a glass melting furnace, in which there exist several flow regimes, multimode heat transfer, physical and chemical reactions, and other related phenomena.

Modeling a glass melting tank provides a means to estimate the effects of many things contemplated by a glass maker. Simulations made with a properly constructed model can, for instance, assist in prescribing or changing the profiles of combustion burners, E-boost power zones, or bubbler flow rates. Changes in pull rate, insulation thickness or type, added wind cooling to outside walls, and surface treatments to alter emissivity of crown materials are just a few other examples of what can be considered with a furnace model.

The effects of various changes can be measured in different ways, too. The overall rate of energy consumption is often a key performance index (KPI). Other KPIs relate to the glass quality. For example, the distribution of residence times for material passing through the melting furnace is important to its operators because, with the shortest times, the material is least likely to have been fully conditioned and, thus, is most likely to have some sort of imperfection such as seeds or cords (Chapter 1.2). Other effects of interest include the maximum temperatures of various refractories, the shear stresses and other

Figure 5 Sketch of a glass melting furnace for the production of reinforcement fiber glass.

conditions contributing to wear, the position of the batch line, and the strength of the backflow of glass against the batch layer.

4.2.2 Interacting Zones

Within a complete furnace model (Figure 5), the common zones included are the glass melt, a batch cover and a foam layer both floating on the top surface of the glass, the hot combustion zone above the glass/batch/foam surface, and the wall zones enclosing the glass and combustion zones. Most of these zones are coupled to each other through exchange of mass, momentum, and energy. The governing equations, boundary conditions, and sources applied to each zone depend on the physical phenomena which occur within each of them, as well as the manner in which they are coupled to the others.

Glass flow in the melter is laminar so that Eqs. (1) and (5–7) apply. To account for the exponential dependence of viscosity upon temperature in a manner, the empirical Fulcher law is often used,

$$\mu = 10^{F_1 + \frac{F_2}{(T + F_3)}}, \quad (15)$$

where F_1 , F_2 , and F_3 depend on the specific glass composition (Chapter 4.1).

Glass flow is forced to a certain extent by the introduction and melting of batch as well as by draining through the throat of the furnace. However, additional forces significantly affect flow patterns. Density changes caused by temperature variations give rise to buoyancy forces, which significantly affect flow patterns in the glass melt. These are accounted for through a body force, which is the last term on the right side of each momentum Eqs. (5)–(7). It is convenient and typical for one of the coordinate directions (e.g. the z -direction) to be aligned with the direction of gravity (or at least opposite to it), so that the body force in its respective momentum equation is represented as

$$B_i = \rho(T)g_i, \quad (16)$$

where $\rho(T)$ is the local density evaluated at the local temperature and g_i represents gravitational acceleration in coordinate direction i (e.g. $g_z = -9.806 \text{ m/s}^2$).

Although the glass is heated from above, which usually results in a stable, vertical temperature gradient, freshly melted material from the batch blanket is relatively cool and dense so that it provides a significant driving force for recirculation in the melt. These buoyancy-driven recirculation velocities can be an order of magnitude larger than those resulting from the forward flow of glass associated with the melter pull. Furthermore, lateral temperature gradients along sidewalls and electrodes provide additional density variations that alter the flow structure. Accounting for flow-inducing density variations thus is essential in the glass melt.

Bubblers also induce significant recirculation of glass caused by forced convection. Buoyancy forces acting on the bubbles cause them to rise, and in doing so, they drag glass upward along with them (Chapter 1.3). With sufficient multiphase modeling techniques, it is possible to track explicitly the flow of both glass and bubbles, but one commonly treats the effects of the glass bubbles more abstractly by applying a momentum source to the appropriate component of the momentum equation in the columnar region associated with each bubbler. That is, the source term will be augmented by a calculated force per unit volume based upon either Stokes' law or a modified version of it [14].

Another means of affecting glass flow is with mechanical stirrers. These can be accounted for in several ways including appropriately scaled volumetric-source terms or through basic boundary conditions where the motion of a wetted wall is prescribed.

Other walls, such as the sidewalls, floor, and electrode surfaces, are simply treated as nonslip boundaries where the fluid velocity is zero. Along the top surface, the glass interacts with the batch, foam and possibly the

combustion fumes. Because of extreme density differences, the influences of foam and combustion fumes on the glass velocities are often assumed to be negligible. The interface between the batch and glass, however, represents a greater challenge, because the momentum exchange between these two zones is not considered negligible, and the interface itself can be difficult to define precisely. Moreover, the batch–glass interface is where freshly melted glass enters the glass domain from the batch layer. Commercial codes treat this interface in different ways. Because it is beyond our scope to cover the details, we will just note that this topic is an area of needed, ongoing development.

Equation (8) governs some of the energy transport in the glass and is the basis for which temperature distributions are determined. Sometimes an enthalpy formulation is used in place of Eq. (8) to couple intrinsically the batch and glass zones with a single equation governing energy transport, in which case temperatures are determined from enthalpy through an appropriate thermodynamic equation of state. Energy is also transported into and through the glass by electrical dissipation and thermal radiation. Joule dissipation is determined from the solution of equation (F) in Table 2. The rate of conversion of electrical energy to thermal energy is represented by the following:

$$E_J''' = \nabla E \cdot \vec{J} = k_e \nabla E^2, \quad (17)$$

where ∇E is the gradient in electric potential, $\vec{J}$ is the current flux density, and k_e is the temperature-dependent electrical conductivity of glass. The Joule dissipation calculated in this way is included in the source term, S_T , in the energy Eq. (8).

Thermal radiation is usually accounted for with the aforementioned Rosseland approximation. But a more detailed accounting of thermal radiation transport is possible with methods such as discrete ordinates, which can, for example, be used to resolve spectral characteristics. Other means are available [3].

The combustion zone above the glass is modeled with the same basic governing equations for momentum and energy conservation, but their application is different for a variety of reasons. Furthermore, transport equations for individual species and thermodynamic state relationships must be applied to account for the reaction of fuel and oxidizer and the creation of products of combustion.

Since the combustion zone is turbulent, all diffusion coefficients are replaced with effective values that account for diffusive-like transport. Hence, it is common to include the k and ϵ equations (D and E in Table 2), from which μ_t is determined. Another difference involves radiation for which the assumption of optically thick media required by the Rosseland approximation is not valid.

Use of discrete ordinates in combustion zones is common. The absorption coefficients required of the DOM depend on species concentrations, especially CO_2 and H_2O , which must be determined from a combustion model that accounts for chemical reactions (i.e. the creation and destruction of molecular species) and the transport of the related species.

Through radiative and convective transport, the combustion gases heat virtually all surfaces, including the walls of the superstructure, the top of the batch layer, the foam, and the glass. Furthermore, these surfaces exchange heat through radiation, which is intrinsically included with a discrete ordinates model. Owing to nonlinearities and to the strong coupling between the various zones and between the various transport equations within a zone, a robust, iterative solver is required to converge on a solution. Typically, iterations are performed until conservation laws are satisfied to within 0.1%, whereas adjustments to URCs are sometimes required to improve convergence.

A model of a glass melting furnace must account for transport not only in the glass and combustion zones, but also within the batch, foam, and walls. Whereas all of these zones must obey the same basic laws of physics, their dissimilar material characteristics require different mathematical treatments. Perhaps the easiest to consider are the walls and other solid objects. The energy Eq. (C) (in Table 2) is applied without the advection term since velocities in the walls are zero. Equation (F) is in addition applied to account for electrical current and Joule heating with the assumption that the electric potential is uniform within an electrode, since its electrical conductivity is orders of magnitude larger than that of any other material.

The batch and foam require additional considerations. Considering first the foam, there are many questions to ask. Where does it exist? How thick is it? Does it absorb radiation from the combustion zone and crown, or does it transmit such radiation? What is the gaseous species within the liquid glass membrane? How large are the foam cells? All of these and other factors will affect transport so that choosing a modeling method presents a significant challenge.

One way to deal with foam is to invoke several simplifying assumptions allowing adjustments based on foam conditions, without requiring detailed information regarding its phenomenological behavior. For example, foam can be treated as a layer of material that acts to impede heat transfer between combustion and glass zones, but ignores advection transport within it. A relatively small number of parameters can be used to characterize the thermal behavior of the foam, which can be adjusted, within reason, to render a well-tuned model.

A similar set of questions arises when considering the batch. Whereas the foam is a two-phase mixture of liquid membranes enclosing gas cells, the batch is a multiphase mixture of solid particles, with interstitial gas and liquid, whose proportions depend on temperature. Unlike in the foam, advective energy transport within the batch zone cannot be ignored without large compromises such that, therefore, the velocity field within the batch layer must be computed. A common way to accomplish it is to treat the batch as a pseudo-fluid with a characteristic viscosity that depends on temperature. The batch is assumed to float on top of the glass and to provide an inflow of melt whenever the temperature at its interface with the glass achieves or exceeds a specified temperature where melting occurs. In this way, the batch zone is treated as another fluid zone governed by equations similar to those of the glass. In addition to providing an inlet flow of melt to the glass zone, the batch zone also produces a small amount of gases into the combustion zone because of the chemical reactions that occur upon melting.

The model described in the preceding paragraphs is an example of a powerful tool constructed from well-defined assumptions and mathematical abstractions. It is summarized in Table 3, which indicates for each zone of the furnace the governing equations and interactions with other zones. The required boundary conditions and other physical parameters needed to specify the operating conditions are summarized in Table 4 where a “coupled” condition indicates an internal boundary condition between two zones where the field variable and associated flux are forced to be the same. In addition, many numerical parameters must be specified in such a way as to bring about a converged solution that satisfies the various conservation principles. Modeling procedures and material properties for glass are discussed in greater detail elsewhere [15].

4.2.3 Post-processing Assessments

One gains additional insights by displaying the computed field variables in a graphical form. A common illustration is a temperature-contour plot, sometimes with flow streaks superimposed. A 3-D rendering of a glass melting furnace (Figure 6.), for instance, clearly shows the batch layer that melts at the glass surface and the flame developing from the rear wall, the extent of these zones being important operational characteristics. An alternative to horizontal flames is presented in Figure 7, where the pair of flames from oxy-fuel burners yield the temperature contours and flow streaks shown for a cross-section of the combustion zone. The fuel and oxidizer react as they flow downward from their nozzles mounted in the furnace crown, and the resulting flame directly impinges on the batch and promotes improved melting efficiency. Similar plots can be drawn on different sections or in different orientations within combustion or glass zones. Furthermore, contour plots of electric potential, Joule dissipation, oxygen concentration, or other field variables can be made directly from the computed solution to provide important insights, especially when comparisons are made between plots drawn for differing possible operating conditions.

Other important information can be gleaned from a converged simulation. For example, quantified values of the energy transfers between the zones illustrated in Figure 5 can be extracted from the simulation results. Examining and comparing these values is very insightful, as it can draw the attention to various things such as how the batch is melted and the sources of inefficiency.

Other quantifiable data that can be directly extracted from a model solution include operating currents and potentials of electrodes, average glass temperature, total volume of batch layer, and temperatures at prescribed

Table 3 Interacting zones of a complete glass melting-furnace model.

Zone	Equations (Table 2)	Radiation treatment	Zone couplings				
			Glass	Batch	Foam	Walls	Combustion
Glass	A,B,C,F	Rosseland					
Batch	A,B,C,F	Surface emissivity	Mass, momentum, energy, electric current				
Foam	C	Surface emissivity and transparency	Energy	Energy			
Walls	C,F	Surface emissivity	Energy, electric current	Energy, electric current	Energy		
Combustion	A,B,C,D,E,G	DOM	Energy	Mass, energy	Energy	Energy	
			Glass	Batch	Foam	Walls	Combustion

locations (e.g. where control or monitoring thermocouples are installed in the actual furnace). These data are essential for validating a model.

4.2.4 Particle Tracking

Additional information is provided by particle tracking and associated analysis as applied to either combustion

or glass (including batch) zones. To track the pathway, inert particles would take if they were introduced into the glass involves additional computation in a Lagrangian framework. Massless particles are commonly used as a kind of virtual flow visualization because the assumption is made that they do not affect the flow of glass. Depending only on glass velocities, their pathways can then be computed from converged solutions of glass flows. To simulate real phenomena, however, particles of specified density and size or gas bubbles can also be tracked, in which cases the velocity of each particle may differ locally from that of the glass because of the effects of gravity.

When massless particles are introduced into a melting tank through a random selection of a large number of starting locations on the batch inlets, their pathways over time can be tracked from the computed field of velocity vectors. When each particle passes through a target plane at the furnace exit, its residence time in the melter can also be recorded. A representative histogram of such times is shown in Figure 8a. The shortest are of primary interest since they are associated with portions of the glass that receive the least amount of thermal conditioning. A more detailed picture can thus be drawn from comparisons made between the pathways of particles with the shortest 0.1% and average residence times (Figure 8b–c), where the so-called short-circuit pathways of the former

(a)

(b)

Figure 7 Combustion zone of a fiber glass melting furnace. (a) Photo of oxy-fuel flames; (b) temperature contours calculated by a simulation model.

contrast with the large recirculation loops followed several times by the latter.

Other mathematical integrations are often performed along particle paths. One example is the dimensionless mixing index, which can be interpreted as the number of times a spherical cord of glass of specified initial diameter d_{ci} would dissolve as it travels along the path of the particle, from beginning to end. This index is defined as

$$I_{mix} = \int_0^{\text{end}} \frac{4 \|\nabla \vec{V}\|^{2/3} \mathcal{D}}{3d_{ci}^{2/3}} d\tau, \quad (18)$$

where $\mathcal{D}$ is the species diffusion coefficient in glass. In a manner similar to that of residence times, a distribution of mixing indices can thus be determined from the massless particle traces, and other similar indices also be computed.

Another analysis involves tracking and particles to account for the dissolution of each particle along its pathway as shown in Figure 9 for particles emanating from the batch layer and disappearing in the glass. The top and side views shown in Figure 9 are of the same melting tank illustrated in Figure 8. A distribution of survival times, average temperatures, and final temperatures can be assembled and compared with distributions gathered from other simulations representing different conditions. Such comparisons can be useful in assessing the likelihood of introducing unmelted batch stones into the

front-end. Similar tracking techniques can of course be applied to gas bubbles.

5 Simulation Data Management

Since modeling has gained wider acceptance and is increasingly relied upon to support important decisions, capturing and cataloging simulation models, the data used for their input, and the calculated results are very important. Managing simulation data has become a challenge for many organizations engaged in process modeling. A good simulation data management (SDM) system allows models to be “recycled” and used again for a different set of operating conditions, and allows different users to access archived models and their data. Furthermore, a good system has cataloging and search features that allow users in need of modeling data to access it quickly, even if they are not familiar with the previous modeling study. That is, not only should a SDM system assist individual analysts to organize their results, but it should serve a larger enterprise, with many people in different and changing roles.

The interactions and associated transfer of information of different organizations within a glass processing enterprise are sketched in Figure 10. Whether simulations are performed to assist a technical-support team or a technology-development effort in R&D, the ultimate

(a)

(b)

(c)

benefactor is the manufacturing operation. Although there are direct interactions between any two of these subgroups, an SDM system can be used to manage data collected and generated by the modeling and simulation activities.

An SDM system improves productivity by keeping data well organized and accessible to authorized individuals at various locations, who may be interested in a summary of results, build a new model based on a previous model, or mine data in search of correlations between certain operating conditions. By keeping official records, the SDM reduces problems of duplicated files or duplicated names of slightly different files. It also contributes to security by controlling access, minimizing the chance of

inadvertently deleting files, and centralizing the backup of these data.

There are numerous ways to implement some kind of SDM system, ranging from a highly structured and well-organized network-attached storage system to highly sophisticated commercial offerings that either resemble product lifecycle management (PLM) systems or are even integrated into a PLM. In addition to administering simulation data, many of these systems also can be used to manage the simulation process, where workflow is defined within collaborative groups, computational resources are shared, and sequential, parametric simulations (e.g. a design optimization exploration) can be conducted with improved effectiveness. These SDM

Figure 10 Central role of simulation data management in sharing of information.

systems are designed to extract metadata from model files. Examples of commonly extracted metadata are methods to characterize viscous effects (i.e. laminar, turbulent $k-\epsilon$, turbulent RSM, etc.), mesh size, mesh type (i.e. hexahedra, tetrahedral, etc.), software version, etc. For glass processing, it is possible and recommended to provide a way to extract metadata associated with the glass process; examples of these include furnace footprint size, pull rate, glass type, batch characteristics, etc. Any organization which has collaborative efforts involved with modeling and simulation should thus implement some kind of data management system.

6 Perspectives

The use of mathematical modeling in other glass industry segments has also increased over the years. Examples of such work can be found in the container, specialty, and float-glass industry for simulations of processes such as refining, homogenizing, tempering, shaping, gas generation [4, 16–18]. Striking results have, for instance, been obtained for containers for which simulations allow the shape and fabrication process to be optimized many times more rapidly (and less expensively) than in the traditional way. Not surprisingly, constructing a model to simulate a glass melting furnace is a larger, more time-consuming task. Obtaining a converged solution while considering the uncertainties associated with material properties is also challenging. Small changes to a validated model can be applied, however, and new simulation results can be computed quickly.

The amount of information that can be extracted from simulation results is appreciated for its value in assessing conditions not possible without computational modeling. Sometimes, a particular post-processing analysis is not desired until well after a simulation has been completed (i.e. weeks, months, or years later), but as long as the simulation data has been preserved, the analysis can be completed quickly.

Although advanced, modeling and simulation of glass processes can be improved. Some of the improvements are related to numerical implementation, but it is often the case that required transport properties cannot be measured without inordinate expense. Some improvements are related to achieving more accurate solutions, whereas other are related to improve post-processing. For example, improved knowledge of heat transfer in a foam could significantly reduce the time required to tune and validate a simulation model (i.e. improved accuracy and efficiency), whereas more information about refractory dissolution or wear could improve post-processing assessments of furnace life.

The batch layer represents an important area whose physics needs to be better understood. The effects of batch constituents (as well as the size and shape of individual particles), the manner in which the batch moves, transmits energy, reacts, and melts into glass need to be understood in a way that can be implemented in a numerical simulation. A similar comment can be made for foam. Despite these shortcomings, simulation results are very useful when applied and interpreted properly. When significant uncertainties exist or if validation fails to reconcile all metrics satisfactorily, then comparisons between simulations cases can be made in a semiquantitative manner, where the simulation results reveal general trends (e.g. increased recirculation, or lowering of exhaust gas temperatures). Results such as these provide guidance that would otherwise be unavailable.

Acknowledgements

The authors thank Glass Service Inc. for sharing nonproprietary model data from which some of the examples presented were taken. Also, they are grateful to their employer, Owens Corning, for supporting their effort to contribute to this volume.

Section II. Structure

Figure 1 The atomic disorder of the glass structure (left) giving way to crystalline order (right): the boundary between a Zr-bearing magnesium aluminosilicate glass and a ZrO₂ crystal that precipitated in it. Bar scale: 5 nm. Abberation-corrected, high-resolution transmission-electron micrograph courtesy Christian Patzig and Thomas Höche.

It is usually stated that the various properties of glasses and melts are determined by the structures of these phases. This statement is thermodynamically incorrect: a melt has a structure that is fixed instead by the minimum of its Gibbs free energy and, thus, by the temperature-dependent balance between enthalpy and entropy factors that are themselves determined by the existing atomic interactions. This is the manner in which the structures of *melts* predicted in theoretical calculations are assumed to be those of *glasses* quenched from some pressure and high temperature.

Structural studies are nonetheless useful either at a small scale, for example, to figure out how the local environment of an ion determines its optical properties (Section VI), or at a larger scale to gain insights on property–composition relationships when the specific influence of chemical entities on the properties of interest can be evaluated in terms of well-defined structural elements such as rings or coordination polyhedra. The method was pioneered in Antiquity by Plato (–428–347): to each of the four elements then acknowledged, he assigned geometrical shapes accounting for their properties, namely the tetrahedron for fire, octahedron for air, icosahedron for water, and cube for earth. Of course, such assignments are no longer purely intellectual constructs; they have an experimental basis. Interestingly, however, one should realize that the first atomic models of glass were devised shortly before any experimental tool was available to determine their structural components (Chapter 10.11). In other words, glass structure represents a good example of a situation where theory not only preceded experiments but also defined their paradigmatic framework.

To set the frame of this second section of the Encyclopedia, a broad overview of the structure of amorphous materials and of associated theoretical models at different length scales is first given by A.C. Hannon for network oxide and chalcogenide glasses, with particular emphasis on the random-network model (Chapter 2.1). Recently, progress in the analytical techniques used in structural studies has been enhanced by the availability of intense sources of electromagnetic radiation, namely lasers and synchrotron facilities. From X-ray diffraction and absorption to vibrational and Mössbauer spectroscopies, these various methods and the information they yield are reviewed by G. Henderson (Chapter 2.2). Whether purposely produced in glass ceramics or formed spontaneously in industrial or natural processes, inhomogeneous glasses are also given increased attention (Figure 1). To determine their microstructure and analyze their constituents at a scale down to the nm range, C. Patzig and T. Höche then present scanning and transmission electron microscopy, analytical tools, and the relevant analytical tools and other ancillary techniques available (Chapter 2.3).

From the results obtained with these methods, the next three chapters focus on the glass structure. Short-range order is dealt with by J.F. Stebbins in a chapter where he defines such concepts as network formers and modifiers, bridging and nonbridging oxygens and their tetrahedral distribution around the network-forming cations they coordinate, and he also discusses how they change with temperature and composition (Chapter 2.4). From the scale of atoms to that of macroscopic bodies, the increasing complexity found at longer distances is then examined by G.N. Greaves who also points out the basic differences found between oxide and metallic systems (Chapter 2.5). Because glasses have generally complex chemical compositions in both industrial and geological contexts, the relationships between the structures of simple and multicomponent systems are finally described by B.O. Mysen in a perspective aimed at understanding composition–property relationships (Chapter 2.6).

Returning to more theoretical aspects, the next chapter by P.K. Gupta stresses with the *constraint theory* the importance of simple topological considerations and of temperature-dependent bond strengths to understand the glass structure and composition–property relationships. To conclude this section, two chapters review the rapid advances made in the growing field of atomistic simulations in two complementary ways. In the Monte-Carlo and molecular-dynamics simulations presented by A. Takada (Chapter 2.8), the interatomic potentials used to simulate the structure and properties of glass-forming systems are determined a priori, with the advantage that up to a few thousand particles can be considered with current computing power. As reviewed by W. Kob and S. Ispas, atomic interactions are determined instead from first principles in the more fundamental and precise *ab initio* approaches, such as density functional theory; the price is that only relatively small systems can be currently investigated (Chapter 2.9). Ascertaining the energetics of a glass-forming melt is fraught with considerable difficulties, however, because phase transformations, in which one is interested, are driven by small differences of typically a few kJ between the very large numbers yielded with significant uncertainties by *ab initio* methods.

Throughout this section the emphasis is generally put on oxide glasses. Metallic glasses are specifically dealt with in Chapter 7.10 and organic polymers in three other contributions (Chapters 8.8–8.10).

Basic Concepts of Network Glass Structure

Alex C. Hannon

ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, UK

1 Introduction

What is a *glass* from a structural standpoint? There are different answers dependent upon whether the emphasis is on structure, preparation methods, or thermodynamic properties. However, a simple structural definition is adopted here, according to which a material must be solid and have a noncrystalline structure to be called a glass.

Put simply, the description of a crystal involves a unit cell, containing a particular arrangement of atoms, which is then replicated periodically in three dimensions to build up the structure as illustrated by the 2-D (two dimensional) representation of Figure 1. Crystal structures have translational symmetry because, if crystallite boundaries are neglected, the environment of a particular atom is the same as that of all equivalent atoms in all unit cells. Contrastingly, a glass lacks translational symmetry and a detailed understanding of its structure requires as much experimental information as possible. In addition to X-ray (XRD) and neutron (ND) diffraction, inelastic neutron scattering and various other spectroscopies (X-ray absorption, infrared, Brillouin, Mössbauer, and X-ray photoelectron spectroscopies) may be used (Chapter 2.1), along with electron microscopy, physical property data (especially density), and theoretical modeling.

As is clear to any reader of this *Encyclopedia*, many types of materials can vitrify if they are solidified rapidly enough to avoid crystallization. Leaving aside metallic glasses (Chapter 7.10) or organic polymers (Chapters 8.7 and 8.8), however, the majority of useful glassy materials are formed by oxides or chalcogenides. This is the reason why this chapter is restricted to these materials and to the elementary concepts that are used to describe their structure.

These structures can be understood well in terms of the continuous random network (CRN) model, first propounded by Zachariasen [1], because the atomic bonds have some covalent (directional) character. The basic features of this model will thus be reviewed and related to fundamental structural information gathered for silica glass, the archetypal glass former, and the “mother” of all amorphous silicates. Because microcrystalline descriptions of glass structures in fact preceded Zachariasen’s model, their basic limitations will also be summarized. The structural changes induced by the addition of so-called network modifiers in oxide glasses will then be discussed at short- and medium-length scales, along with the intermediate character of some oxides that may act as glass formers only when combined with some modifiers. Finally, the manner in which network glasses can depart from Zachariasen’s model will be illustrated with chalcogenides.

List of Acronyms

2-D	two dimensional
BO	bridging oxygen
CRN	continuous random network
FSDP	first sharp diffraction peak
IRO	intermediate-range order
LRO	long-range order
MD	molecular dynamics
MRN	modified random network
MRO	medium-range order
NBO	non-bridging oxygen
ND	neutron diffraction
NMR	nuclear magnetic resonance
RMC	reverse Monte Carlo
SRO	short-range order
v-SiO ₂	vitreous SiO ₂
XRD	X-ray diffraction

2 The Zachariasen–Warren Random Network Model

The structure of oxide and chalcogenide glasses is usually described by the Zachariasen–Warren random network model, thus termed because it was proposed by Zachariasen [1] in 1932 and subsequently supported by early XRD studies of glass structure made by Warren and coworkers (Chapter 10.11, [2]).

This model is easily understood with reference to the structure of a 2-D A_2O_3 oxide glass (Figure 2), where the local structure is very well defined in terms of rigid triangular AO_3 units within which there is almost no variation in the bond lengths and angles. The way in which the units connect together to form a noncrystalline structure is described by a set of rules for glass formation, postulated by Zachariasen:

- 1) An oxygen atom (O) is not linked to more than two network-forming cations (A).
- 2) The coordination number, n_{AO} , of oxygen around the network-forming cations must be small, i.e. 3 or 4 (where the coordination number of an atom simply means the number of other atoms that are within a certain distance from it).
- 3) The oxygen polyhedra should share corners with each other, not edges or faces.
- 4) For a three-dimensional network, at least three corners of each polyhedron must be shared.

For the 2-D illustration of Figure 2, the coordination number for the triangular AO_3 units is three, thus satisfying the second rule. Two AO_3 units are connected to each other by the sharing of a common oxygen atom, so that the first rule is satisfied. The third rule is also satisfied, since each pair of connected units shares only one common oxygen, not two (edge-sharing), or three (face-sharing). Even though this example is a 2-D structure, it

Figure 2 Two-dimensional representation of a random network for a composition A_2O_3 [1]. Small dark spheres: A atoms; large light spheres: oxygens.

also satisfies the fourth rule, since the AO_3 units are three-connected. In fact, it is well established that real glasses such as B_2O_3 [3] and As_2O_3 [4] can form three-dimensional structures based on three-connected structural units.

It should be emphasized that the random nature of the structure does not arise from disorder within the basic structural units because the distributions of bond lengths and bond angles within them can be very narrow, as in a crystal structure. Instead, there is a wide distribution of bond angles (e.g. $A-\hat{O}-A$ in Figure 2) leading to a distribution in sizes and shapes of the rings formed by the connections between the AO_3 units. The noncrystalline nature of the structure arises from this wide distribution of bond angles.

As will become clear later, not all real network glasses obey all of Zachariasen's rules. Nevertheless, these rules provide a basic philosophical framework and a valuable starting point from which the structure of real glasses can be described.

A comparison of the crystalline structure of Figure 1 with the random network of Figure 2 shows the similarity

and difference between the two. Both types of structure have *short-range* order (SRO) when distances similar to the bond lengths are considered. In fact, SRO arises naturally from the finite sizes of atoms and their mutual bonding so that it exists in all condensed phases, be they liquid, glassy, or crystalline. The fundamental difference is that only crystals exhibit *long-range* order (LRO), extending over distances that are large compared to interatomic spacings (Figure 1), whereas glasses (Figure 2) and liquids are by definition isotropic because their structure is on average the same in any direction.

3 Silica – The Archetypal Glass

Vitreous silica, $v\text{-SiO}_2$, is the archetypal example of an oxide glass. Its basic structural unit is a highly regular tetrahedron, with a silicon atom at the center and an oxygen atom at each of the four vertices, which is denoted as $\text{SiO}_{4/2}$ because each oxygen is bonded to two different silicons. The Si–O bonds are all very close in length to 1.608 Å [5], and the O–Si–O bond angles are all very close to the ideal tetrahedral value of 109.47° . Because $\text{SiO}_{4/2}$ tetrahedra are connected together by the sharing of a bridging oxygen (BO) atom (Figure 3), the Si–O–Si bridge is characterized by three angles: the Si–O–Si bond angle, θ , and the two torsion (dihedral) angles, δ_1 and δ_2 . There is a broad distribution of bond angles (centered at $\sim 144^\circ$), but little or no preference for any particular value of the torsion angle. Hence, the tetrahedra connect together to form a network that is both *continuous* (i.e. it can fill all of three-dimensional space without a break in the continuity of the network) and *random* (i.e. it is

Figure 3 Connection of two corner-sharing $\text{SiO}_{4/2}$ tetrahedra by a bridging oxygen, defining the Si–O–Si bond angle, θ , at the bridging oxygen, and the torsion (or dihedral) angles for the two tetrahedra, δ_1 and δ_2 . Small dark spheres: silicons; large light spheres: oxygens. Shortest interatomic distances indicated by dashed arrows.

not periodically repeating and, thus, not crystalline). This is why a structure of this type is often called a CRN.

Initially, it was not clearly established whether a CRN constructed in this way could indeed fill three-dimensional space without the development of strains or the eventual breaking of bonds. An important step thus occurred in the 1960s when the construction of large ball-and-stick models showed that it is indeed possible to build a large tetrahedral network that is both continuous and random. The most influential was constructed by Bell and Dean [6] for silica with a total of 614 atoms (Figure 4), which appeared to form a three-dimensional CRN structure through the sharing of oxygen bridges between $\text{SiO}_{4/2}$ tetrahedra (Figure 4, inset). Ball-and-stick methods of modeling the atomic structure of glasses are rarely used nowadays, and computer-based methods are extensively used, for example, Monte Carlo, molecular dynamics (MD), or reverse Monte Carlo (RMC) simulations (Chapter 2.8, [7]).

Experimentally, evidence for a random SiO_2 network is provided by the diffraction patterns measured by both XRD [2, 8] and ND [5, 9], which has some advantages over XRD for the study of disordered materials (Chapter 2.2). Whereas the peaks observed in the diffraction patterns of

crystals are sharp, those for glasses are broad (Figure 5a). These patterns are conventionally displayed as a function of momentum transfer, Q , otherwise known as the magnitude of the scattering vector. A standard analysis [10] is to obtain a correlation function from a suitable Fourier sine transform of the experimental data from reciprocal to real space (Figure 5b). The result essentially shows the distribution of interatomic distances in the measured sample, each of its peaks corresponding to a commonly occurring interatomic distance. For $v\text{-SiO}_2$, the first two peaks in the correlation function arise from the Si—O bond length and the O—O distance within $\text{SiO}_{4/2}$ tetrahedra, respectively. Since these peaks are as sharp

as for α -quartz, both distances are as well defined in the glass as in the crystal. Within the limits of what is achievable experimentally, the Si—O and O—O coordination numbers determined from the areas of these peaks are essentially four and six, as expected for a fully connected CRN of $\text{SiO}_{4/2}$ tetrahedra (Figure 3).

Because of LRO, there are further sharp peaks at longer distances in the correlation function of a crystal (Figure 5b). In contrast, these features rapidly become less well defined for a glass so that it becomes harder to determine structural information involving longer correlation lengths. For instance, the third peak in the function of $v\text{-SiO}_2$ arises from the two silicon atoms in a

Figure 5 Diffraction results for α -quartz and $v\text{-SiO}_2$. (a) Neutron diffraction measurements of their distinct scattering [9] compared with the X-ray diffraction data for $v\text{-SiO}_2$ [8]. Position of the first sharp diffraction peak indicated at $Q_1 \approx 1.52 \text{ \AA}^{-1}$. (b) Neutron correlation function for α -quartz and $v\text{-SiO}_2$, and X-ray correlation function for $v\text{-SiO}_2$. Approximate positions of the short distances for a pair of connected tetrahedra indicated as $(\text{Si-O})_1$, and so on (same notation as in Figure 3).

Figure 6 Comparison between the Si—O—Si bond angle distributions, $V(\theta)$, in SiO_2 glass, obtained from an analysis of the X-ray correlation function [11] (continuous line) and in a recent NMR study [12] (dashed line).

connected pair of $\text{SiO}_{4/2}$ tetrahedra. This peak is broadened due to variations in the angle θ (Figure 3), which lead to the random nature of the structure. The distribution of Si—O—Si bond angles, θ , has been extensively investigated. From fits made to their X-ray correlation function, Mozzi and Warren [11], for instance, found a most probable bond angle of 144° with an average value of 147.9° and a standard deviation of 12.7° (Figure 6). In a recent nuclear magnetic resonance (NMR) study, a narrower distribution was deduced with values of 147.1 and 11.2° , respectively [12].

A nice example of the structural information that can now be drawn from advanced forms of microscopy is provided by v- SiO_2 . For example, the amorphous region of a 2-D layer of SiO_2 on a graphene support has recently been imaged at the atomic scale (Figure 5b in Chapter 2.5). A bi-tetrahedral layer is visible in the image where the nodes are the locations of Si atoms. Hence, the view is that of a layer of faces of tetrahedra whose similarity with the 2-D representation of a random network shown in Figure 2 is striking.

4 Microcrystalline Models

Early in its study, the structure of silica glass was described in terms of the so-called microcrystalline model [13], and hence it is useful to mention it briefly here. Its starting point is that, although crystals have diffraction peaks that are much narrower than for glasses (Figure 5a), significant broadening is observed if crystallites are very small, in accordance with the Scherrer equation, $\Delta Q = 2\pi K/L$, which relates the width of a Bragg peak

ΔQ to the crystallite dimension L and to a shape factor K (~ 1).

To account for its broad diffraction peaks, one might thus describe a glass in terms of very small crystallites. However, a problem with the model is that to explain the large widths of the observed glass diffraction peaks, the crystallite size should typically be on order of $5 \text{ \AA}$, a value similar to unit-cell dimensions. Philosophically, it makes no sense to consider crystallites as ordered entities if they contain only one unit cell, since there would be no translational symmetry. Furthermore, with such small crystallites, a crystalline powder would be composed almost entirely of grain boundary material, which by definition differs structurally from the bulk. Hence, microcrystalline models cannot provide a description of the structure of most of the material in the glass. For these two reasons, they need not be considered further.

5 Modifiers and Non-Bridging Oxygens

5.1 The Role of Network Modifiers

The only oxides that can readily form glasses on their own are SiO_2 , GeO_2 , B_2O_3 , P_2O_5 , and As_2O_3 . They are known as glass or network *formers*. Their structures are well described as random networks (Figures 2 and 4), involving well-defined oxygen coordination polyhedra, namely $\text{SiO}_{4/2}$ tetrahedra (Figure 7c), $\text{GeO}_{4/2}$ tetrahedra (Figure 7c), $\text{O}=\text{PO}_{3/2}$ tetrahedra (Figure 7d), $\text{BO}_{3/2}$ triangles (Figure 7a), and $\text{AsO}_{3/2}$ trigonal pyramids (Figure 7b). The ability to vitrify readily arises as a consequence of the network structure.

If a second oxide with weaker, ionic bonding is added, then it can lead to some depolymerization of the network, as shown schematically for Na_2O by the following reaction.

The additional oxygen introduced as Na_2O is accommodated in the network by the breaking of bridges; a single BO, bonded to two silicon atoms, is replaced by two non-bridging oxygens (NBOs), each bonded to one silicon atom. In this depolymerization reaction, the NBOs are shown with a negative charge, balancing the positive charges on the Na^+ cations. As sketched in a 2-D representation (Figure 4 of Chapter 2.4), such second oxides modify the network structure of the glass former, but do not become part of the network itself, hence their name of *modifiers*. Alkali and alkaline earth oxides are the most

Figure 7 Structural units in network glasses: (a) $\text{AO}_{3/2}$ triangle; (b) $\text{AO}_{3/2}$ trigonal pyramid; (c) $\text{AO}_{4/2}$ tetrahedron; (d) $\text{O}=\text{PO}_{3/2}$ tetrahedron (double bond $\text{P}=\text{O}$ shown dashed); (e) $\text{AO}_{4/2}$ pseudo-trigonal bipyramid (disphenoid); (f) $\text{AO}_{5/2}$ trigonal bipyramid; (g) $\text{AO}_{5/2}$ square pyramid-based unit; (h) $\text{AO}_{6/2}$ octahedron.

Figure 8 Neutron correlation function for lithium disilicate glass [14]. The $\text{Li}-\text{O}$ shaded peak is negative, making it readily identifiable in comparison with the positive $\text{Si}-\text{O}$ and $\text{O}-\text{O}$ peaks (Figure 5b).

common examples. They cannot form a glass by themselves, but only in combination with a glass former.

This structural view emerged from early XRD studies where the modifier cations M were regarded as being stuffed into available holes in the network. However, subsequent studies have shown that modifiers actually have a well-defined coordination shell with a fairly narrow distribution of $M-\text{O}$ bond lengths, as exemplified in Figure 8 by the neutron correlation function for lithium disilicate glass where the $\text{Li}-\text{O}$ bond peak is clearly apparent [14]. In contrast, however, there is little

evidence that the oxygen coordination polyhedra of modifier cations generally have a well-defined geometry, which would involve a narrow distribution of $\text{O}-\hat{M}-\text{O}$ bond angles.

Glass formers have strong bonds and a low coordination number, the tetrahedral value of four being the most common, whereas modifiers have weak bonds and coordination numbers typically greater than four. These high values, combined with a lower cation charge, mean that $M-\text{O}$ bonds are much weaker and, hence, that all glass properties are profoundly altered by the introduction of modifiers. For example, the addition of Na_2O generally reduces viscosity, glass transition temperatures, and melting conditions.

There are other oxides known as *conditional* glass formers, because their structural role is intermediate between those of formers and modifiers. They do not readily form a glass on their own, but can readily do so in combination with a modifier as, for example, has been known for over a century for Al_2O_3 in $\text{CaO}-\text{Al}_2\text{O}_3$ melts. In addition to Al_2O_3 , other notable conditional glass formers are Ga_2O_3 , Sb_2O_3 , TiO_2 , TeO_2 , V_2O_5 , Nb_2O_5 , and Bi_2O_3 . Because they have a geometrically well-defined coordination shell, conditional glass formers give rise to structures that are well described as random networks. For instance, the networks formed by binary aluminate and gallate glasses are based on $\text{AlO}_{4/2}$ and $\text{GaO}_{4/2}$ tetrahedra (Figure 7c), respectively. On the other hand, in more complex systems involving a glass former, aluminum can occur with mixed four-, five-, and six-coordination as clearly revealed by ^{27}Al NMR spectra,

which are very sensitive to Al speciation. Antimonite glasses form a network based on $\text{SbO}_{3/2}$ trigonal pyramids (Figure 7b). Contrastingly, tellurite glasses form a network based on two different units, $\text{TeO}_{4/2}$ pseudo-trigonal bipyramids (or disphenoids, Figure 7e) and $\text{TeO}_{3/2}$ trigonal pyramids (Figure 7b). Similarly, vanadate glasses involve a mixture of VO_4 and VO_5 units (Figure 7f and g). Also, binary niobate glasses seem to be dominated by five-coordinated NbO_5 units. In alkali titanate glasses, the network is formed from $\text{TiO}_{4/2}$ tetrahedra, although five-coordinated $\text{O}=\text{TiO}_{4/2}$ units (cf. Figure 7g, but with a terminal apical oxygen) and octahedral TiO_6 units (Figure 7h) can be found in more complex glasses.

As listed in Table 1, the most commonly studied oxides can thus be classified structurally according to their role in the formation of glass networks [15]. This classification is not exact, but nonetheless represents a useful guide; for example, TeO_2 and Sb_2O_3 have been classified as conditional glass formers, but actually both vitrify if quenched rapidly enough. Besides, some oxides with a lone-pair cation, such as PbO , are listed as both a modifier and a conditional glass former. Depending on whether or not the lone-pair of electrons is stereochemically active, the oxide acts as a network former (with a low coordination number) or as a modifier (with a high coordination number).

5.2 The Modified Random Network Model

In the aforementioned depolymerization reaction, an NBO is conventionally depicted with a negative charge to balance the positive charge on the Na^+ modifier cation, shown to indicate ionic bonding between the anions and cations. Although this reaction only shows two NBOs adjacent to the Na^+ , the coordination numbers of modifier cations are actually larger, typically greater than four.

Table 1 Structural classification of commonly studied oxides in glasses. Frequently found M—O coordination numbers (where M indicates the cation) are given in brackets.

Glass formers (network formers)	Intermediates/Conditional glass formers	Network modifiers
B_2O_3 (3,4)	Al_2O_3 (4,5,6)	Li_2O (4,5)
SiO_2 (4)	Ga_2O_3 (4,5,6)	Na_2O (4–7)
GeO_2 (4,5,6)	Sb_2O_3 (3,4)	K_2O (5–9)
P_2O_5 (4)	TiO_2 (4,5,6)	Cs_2O (6–12)
As_2O_3 (3)	TeO_2 (3,4)	MgO (4,5)
	V_2O_5 (4,5)	CaO (~6)
	Nb_2O_5 (5)	SrO (4–7)
	Bi_2O_3 (4–6?)	ZrO_2 (~6)
	ZnO (4)	MnO (4–6)
	PbO (3,4,5)	PbO (6–12)
	SnO (3,4,5)	SnO (6–12)
	Ti_2O (~3)	Ti_2O (6–12)

It is thus inevitable that the modifier cations are clustered in some way. According to Greaves' modified random network (MRN) model (Chapter 2.5), the modifiers coalesce into channels if their content exceeds a percolation limit. There are thus two interlacing sublattices: the network regions constructed from network formers and the inter-network regions made up of modifiers (see Figure 8a in Chapter 2.5). Such a microstructure has important consequences for the physical and transport properties (e.g. ionic conductivity).

5.3 Network Connectivity and Q-species

In pure SiO_2 glass, all silicon atoms are bonded to four BOs. However, as a modifier is added, the average number of BOs bonded to a silicon decreases, and there is a corresponding increase in the number of NBOs bonded to a silicon. Experimental evidence indicates very strongly that all of the silicon atoms remain tetrahedrally coordinated in almost all silicate glass systems. Thus, when a modifier is added, there is a mixture of Q^n tetrahedra, where n and $4 - n$ are the numbers of BOs and NBOs bonded to the silicon, respectively (cf. Chapter 2.4). Hence, Q^4 represents a silicon atom bonded to four BOs (as in pure SiO_2 glass), Q^3 a silicon atom bonded to three BOs and one NBO, and so on. The abundances of these species can be quantitatively determined by ^{29}Si NMR measurements as illustrated in Figure 9 for lithium silicate glasses [16]. The distribution of Si sites between the different Q^n -species is not statistically random, but, to first approximation, follows instead a binary rule: the addition of small amounts of modifier to the glass leads to the conversion of Q^4 to only Q^3 until composition $J = \text{Li}_2\text{O}/\text{SiO}_2 = 0.5$, equivalent to 33.3 mol % Li_2O , is reached, at which all silicons are on Q^3 sites; then follows a region of composition $0.5 < J < 1.0$, where the addition of more modifier leads to the conversion of Q^3 sites to only Q^2 , and so on. This evolution has important consequences for the connectivity of the silicate network. For example, a glass with a majority of Q^2 sites is dominated by chains (or isolated rings) of silicon tetrahedra. When $J > 1.0$ (i.e. for less than 50 mol % SiO_2), the 3-D connectivity of the structure breaks down. These materials are known as *invert* glasses since their structure is dominated by the bonds to the modifier cations, thus inverting the roles of these cations.

5.4 Change of Coordination Number

A detailed discussion of bonding and the manner in which it determines atomic coordination numbers and polyhedra is beyond the scope of this chapter. Although of very limited practical use, the 8- N rule provides a very simple illustration of an approach to bonding. It states

Figure 9 Deviations of the relative abundance of Q^n -species in lithium silicate glasses (points) from an idealized binary distribution (continuous lines) as a function of the $\text{Li}_2\text{O}/\text{SiO}_2$ ratio, J [16]. Shading of the points indicating the original ^{29}Si NMR experimental data (see key on the figure):

$\triangle$ - Q^4 , $\circ$ - Q^3 , $\diamond$ - Q^2 , $\square$ - Q^1 , ∇ - Q^0 .

that the coordination number of a covalently bonded atom with N valence electrons is $8-N$. Now, the electronic configurations of silicon and oxygen are $[\text{Ne}] 3s^2 3p^2$ and $[\text{He}] 2s^2 2p^4$, respectively, so that with 4 and 6 valence electrons these elements should have coordination numbers of 4 and 2, respectively, as actually observed in $\nu\text{-SiO}_2$ and in silicate glasses at zero pressure. Silicon atoms with a higher coordination number do occur, but usually under high pressure, the only known exception being alkali phosphosilicate glasses (e.g. $\text{Na}_2\text{O-P}_2\text{O}_5\text{-SiO}_2$), in which the presence of some six-coordinated silicon has been established [17].

For other glass formers, a higher cation coordination can in contrast occur with ease. For example, in pure B_2O_3 glass, all boron atoms are three-coordinated, as depicted for a fragment of the network in Figure 10a. However, there are two alternative ways in which a modifier such as M_2O may be accommodated in a borate network. The additional oxygen from a M_2O unit can be incorporated into the network either by conversion of one BO to two NBOs (Figure 10b), as occurs in silicates, or by conversion of two borons from three- to four-coordination (Figure 10c). Because ^{11}B NMR is sensitive to the presence of four-coordinated boron, the average coordination number, n_{BO} , can be measured over very wide composition ranges. For $x\text{Li}_2\text{O} \cdot (1-x)\text{B}_2\text{O}_3$ glasses (Figure 11), n_{BO} increases with x , from 3 for B_2O_3 itself, to a maximum value of 3.44 ± 0.01 at 35–38 mol % Li_2O , and then falls for further increases in the Li_2O content [18].

This variation can be reasonably accounted for by a simple charge-avoidance model [19], in which additional oxygen is incorporated into the borate network by the conversion of BO_3 units to BO_4 provided that centers of negative charge are not directly connected. These

Figure 10 The two differing effects of the addition of a network modifier cation M^+ on the borate network. (a) Fragment of the network of pure B_2O_3 glass (small spheres are B atoms, and large spheres are O atoms). (b) Formation of non-bridging oxygens. (c) Formation of four-coordinated boron atoms.

centers are not only NBOs but also BO_4 units since these have a net negative charge. For small amounts of modifier, the formation of BO_4 units causes n_{BO} to be equal

Figure 11 Boron-oxygen coordination number, n_{BO} , for lithium borate glasses, $\text{Li}_2\text{O}-\text{B}_2\text{O}_3$, as determined by ^{11}B NMR (points) [18], compared with the prediction from a charge-avoidance model [19].

to $3 + x/(1 - x)$. At larger contents, however, NBOs form instead so that n_{BO} falls back toward a value of three. Similarly, the thermophysical properties of borate glasses show a maximum (or minimum) as modifier is added to the glass known as the *borate anomaly*.

Pure germania glass, GeO_2 , forms a tetrahedral network, similar to that of silica, but with a smaller average $\text{Ge}-\text{O}-\text{Ge}$ bond angle. As for borates, however, the addition of a modifier is accompanied by a growth and then a decline in the value of the average coordination number, n_{GeO} , and the thermophysical properties also show a maximum (or minimum). Originally, this *germanate anomaly* was ascribed to the formation of octahedral (i.e. six-coordinated) germanium atoms. Compared to the borate anomaly, however, evidence concerning the structural aspects of the germanate anomaly is much less plentiful because germanium nuclei are not usefully accessible to NMR. For cesium germanate glasses, ND measurements [20] show that as Cs_2O is added to GeO_2 glass, n_{GeO} increases up to a maximum value of 4.36 for 18 mol % Cs_2O , and then falls for further increases in the Cs_2O content (Figure 12). The additional oxygen from an M_2O unit can lead to a growth in n_{GeO} either by converting one GeO_4 into a GeO_6 unit, or by converting two GeO_4 units into GeO_5 units, and both mechanisms are possible in principle. However, the variation of n_{GeO} for cesium germanates is much better predicted by a charge-avoidance model if the higher germanium coordination number is five, rather than six. Nevertheless, evidence is beginning to emerge that the preferred higher Ge coordination in germanate glasses may depend on the modifier cation.

Figure 12 Germanium-oxygen coordination number, n_{GeO} , for cesium germanate glasses, $\text{Cs}_2\text{O}-\text{GeO}_2$, as determined by neutron diffraction [20], compared with the predictions of charge-avoidance models in which the higher GeO_n coordination is either 5 or 6.

6 Intermediate-Range Order

Until this point, only SRO has been discussed, along with the structural characteristics that arise directly from interatomic bonding, namely bond lengths, coordination numbers, bond angles, and coordination polyhedra. Even though LRO is by definition lacking in glasses, some ordering exists at length scales between SRO and LRO. It is known as *intermediate-* or *medium-range order* (IRO or MRO).

It must be acknowledged that IRO is much harder to probe experimentally than SRO and is, therefore, much less well known. To investigate it, structural modeling may in fact be required to complement direct experimental evidence. This order can be variously characterized in terms of clustering (e.g. Greaves' MRN, cf. Figure 8a in Chapter 2.5) or free volume, for example, but the most widespread approach is to consider the rings that are defined by connected polyhedra in the CRN. Whereas a crystal contains only very few different rings (e.g. the 2-D crystal of Figure 1 contains only six-membered rings), the rings in a CRN have a wider and more varied distribution of sizes (Figures 2 and 4).

Although this ring-size distribution in general cannot be directly addressed experimentally, there are some notable exceptions. A case in point is v-SiO_2 , whose Raman spectrum shows two sharp peaks, at 495 and 606 cm^{-1} , known as D-lines, because they were initially

assigned as defect modes. It is now clear, however, that they represent instead the breathing modes of highly regular four-membered rings and planar three-membered rings, respectively [21]. Although these modes give rise to distinctive peaks in the Raman spectrum, theoretical analysis shows that the concentrations of these highly regular rings are actually low, with fractions of oxygens in regular four-membered rings and planar three-membered rings estimated as 0.36% and 0.22%, respectively [22].

Likewise, borate networks exhibit different rings of $\text{BO}_{3/2}$ and $\text{BO}_{4/2}$ units, which have no (or very few) internal degrees of freedom, and thus have very clear signatures in vibrational spectra. The best known is the boroxol group, a highly planar ring of three $\text{BO}_{3/2}$ units, which was first detected in B_2O_3 glass (Chapter 10.11). Much experimental evidence from a number of techniques [3] shows that in B_2O_3 glass about 75% of boron atoms are in boroxol groups, while the remainder are in individual $\text{BO}_{3/2}$ triangles. The boroxol group is in fact so well defined that it can be regarded as a larger structural unit, a superstructural unit, as illustrated in a 2-D representation of the structure of B_2O_3 glass (Figure 13). As a modifier is added to B_2O_3 , boroxol groups become less abundant, but they are replaced by other types of borate superstructural units [19].

Figure 13 Two-dimensional representation of the boroxol ring model for the structure of B_2O_3 glass [3]; a randomly ordered network of boroxol groups and independent BO_3 triangles. Shaded areas indicating a typical boroxol group (B_3O_6) and independent triangle (BO_3), respectively.

Another approach to IRO is to study the first peak in the diffraction pattern, the so-called first sharp diffraction peak (FSDP), see Figure 5a. The FSDP has been treated as especially important by many workers, perhaps because it is related to the order with the longest period in real space. However, Salmon has pointed out that the longest range ordering in glasses actually gives rise to the second peak in the diffraction pattern (the so-called principal peak) [23]. In the past, it was often popular to regard the FSDP as evidence of crystal-like layers in the glass, because the peak position, Q_1 , is similar to the position of the first (00ℓ) reflection arising from layers in a closely related crystalline phase. However, it is now clear that the FSDP arises from correlated voids in the network [24]; a more easily understood view of this idea is to regard the FSDP as arising from the approximate repetition of the walls of the three-dimensional cages formed by the CRN [25].

7 Chalcogenide Glasses

Although chalcogenide glasses, i.e. glasses containing one or more chalcogenide elements, sulfur, selenium, and tellurium, but no oxygen, are dealt with in Chapter 6.5, it is useful to discuss them briefly here because their random network structures differ from those of oxides by contravening Zachariasen's rules for glass formation.

Oxide glasses are completely ordered chemically, so that bonding occurs only between unlike atoms, i.e. oxygen anions only bond to cations, and cations only bond to oxygens. This is not the case for chalcogenide glasses, in which like atoms can bond. For example, in Ge—Se glasses, homopolar Ge—Ge or Se—Se bonds coexist with heteropolar Ge—Se bonds. In contrast to the single stoichiometric SiO_2 composition of silica glass, chalcogenide glasses form over a wide compositional range, as exemplified by $\text{Ge}_x\text{Se}_{1-x}$ glasses, which form in the range $0 < x < 0.42$. Some homopolar bonds are found even at the stoichiometric composition GeSe_2 , as depicted in Figure 14 where the connectivity of a fragment of a Ge—Se network is sketched: Ge atoms are tetrahedrally bonded to four other Se or Ge atoms, whereas Se atoms are bonded to two other Ge or Se atoms. Nevertheless, there is a strong preference for chemical order so that the measured coordination numbers for the Ge—Ge and Se—Se homopolar bonds in GeSe_2 are 0.25 and 0.20, respectively [26]. In Figure 14, the number of homopolar bonds has thus been exaggerated for the purpose of illustration.

Another difference from oxide glasses is that edge-sharing may occur between the structural units. For example, in Ge—Se glasses, a significant number of $\text{GeSe}_{4/2}$ tetrahedra share an edge with another

Figure 14 Network connectivity for a Ge—Se glass with a composition close to GeSe_2 . Pair of edge-sharing $\text{GeSe}_{4/2}$ tetrahedra shown at the top of the figure. Homopolar Ge—Ge and Se—Se bonds represented by a double line.

tetrahedron (see Figure 14), the proportion being 34% in GeSe_2 glass [26]. A noteworthy consequence is the existence of unusually short Ge—Ge distances, which are readily observed by diffraction and also, thanks to a specific vibrational mode, by Raman spectroscopy. Furthermore, some chalcogenide glasses contain molecular units as well as network material. For example, As—S glasses with high S content contain sulfur rings, such as S_8 , while As—S glasses with high As content (~40 at. % As) contain entities such as the As_4S_4 molecule that constitutes the mineral realgar, and others.

This variable composition of chalcogenide glasses leads to variations in the connectivity of the network, and hence in the rigidity of the network. It is predicted by constraint theory (see Chapter 2.8) that the network undergoes a transition from a floppy state to a rigid state when the average coordination number increases through a value of about 2.4 [27], with a major influence on the physical properties.

8 Perspectives

For crystalline materials, the structure is formed from exact repetitions of a huge number of identical (or almost identical) unit cells. Thus, for the most part, a structure solution simply requires the determination of the positions of the relatively very small number of atoms in

the unit cell. The methods of crystallography are immensely powerful so that diffraction methods are pre-eminent in this respect.

Contrastingly, glass is by definition noncrystalline. To determine the statistical distributions of its structural parameters, such as bond length, bond angle, ring size, and so on, structural studies have few of the advantages enjoyed by crystallographers for crystals. Because the amount of information that can be obtained from a single experiment on a glass is small, structural studies are much slower to proceed for glasses than for crystals, and researchers have to fight for each grain of information. In view of this challenge to obtain reliable information, in past decades it has been necessary for researchers to become expert in a particular experimental technique to achieve reliable progress. Nowadays, however, not only are most experimental probes of glass structure well established but their capabilities are steadily being improved as well. It is thus becoming possible to use a number of experimental methods well, so that significant progress is likely to be made by the increasing application of multi-technique methods to the same set of glass samples; for instance, a combination of ND, XRD, NMR, and Raman scattering can reveal a more complete description of the structure of a glass. With the steady improvement of experimental methods and their interpretation, and such a growing use of multiple techniques, it is likely that gradually more complex glasses will be studied with a growing resolution, and that modeling will have in parallel an increasingly significant role in improving our understanding of glass structure.

Acknowledgements

I am most grateful to Dr. Kevin Knight for crystallographic guidance, and to Professor Adrian Wright for many illuminating discussions about the structure of glass. Thanks are also due to Dr. Shinji Kohara for providing X-ray diffraction data on silica glass. Dr. Gavin Mountjoy of the University of Kent is thanked for his careful reading of the text, and advice for its improvement.

Structural Probes of Glass

Grant S. Henderson

Department of Earth Sciences, University of Toronto, Toronto, Ontario, Canada

1 Introduction

The atomic arrangements that make up the structure of a condensed phase can be probed only with particles or electromagnetic radiation that penetrate into the material and interact with its atoms in such a way that analysis of the changes they undergo yield the specific information sought after. Probably the most basic information is relative atomic positions, which can be derived from X-ray and neutron diffraction experiments because groups of atoms may act as gratings with respect to radiation whose wavelengths are in the Ångström-range of interatomic distances. Alternatively, all other structural probes rely on the exchange of electromagnetic energy in certain frequency ranges to yield information not on the bulk structure of the material, but on individual types of atoms or groups of atoms. As a first example, absorption of X-rays by electrons at eV-energies probes the effects of interatomic bonding on the electronic levels of a given atom and, thus, the environment of this atom and even its redox state. As a second example, similar information may be derived for appropriate transition metal elements with Mössbauer spectroscopy from interactions at higher energies of gamma rays with atomic nuclei. A summary of the methods presented in this chapter along these lines is given in Table 1.

Regardless of the method used, probing atomic structure is much easier for crystals than for amorphous materials. To “solve” the structure, one only requires knowledge of the unit cell as defined by the crystallographic axes (a , b , c) and angles (α , β , γ), the lattice type (P, F, I, A, B, C, H, R), the symmetry associated with both the unit cell (point group) and the lattice (space group),

and the positions of the atoms relative to the origin of the unit cell. One *does not need* to determine the position of *all the atoms* in the structure, but only the minimum number required by the point group symmetry.

Solving the structure of an amorphous material such as glass, on the other hand, currently is not possible and is unlikely in the foreseeable future because of the lack of long-distance atomic periodicity. Hence, one cannot define a unit cell, a lattice, or their associated symmetry that would enable reproduction of the positions of atoms without having to determine the explicit location of all the atoms in three-dimensional space. In essence, *glasses have an infinite unit cell* so that “solving” the structure would require knowledge of the position of every atom, an impossible task.

Nevertheless, it is possible to probe a great many structural features if one keeps in mind that the discrete values of interatomic angles and distances existing in crystals give way in glasses to continuous distributions that can be characterized by their shapes, widths, and maximum or averaged values. In addition to these parameters that characterize the bulk structure of the glass, information pertaining to specific atoms can also be gathered, such as the coordination polyhedra of the various constituents of the material.

Because the structure of a glass represents that of the solid “frozen-in” at the glass transition, it is also important to investigate the marked temperature-induced structural changes that take place in melts at higher temperatures. In this regard, two cases should be distinguished depending on the differences between the experimental timescale of the method and the rate of structural change of the melt. If the former is very short with respect to the latter, then the result will be a snapshot of a solid-like structure; if it is long, the result will represent a time-averaged structure that brings little information on the individual features that are averaged (see Section 4).

Table 1 Summary of techniques used to determine various features of glass structure.

Technique	Energy (eV)	Frequency (Hz)	Wavelength (nm)	Process	Information obtained
X-ray diffraction	0.1–100 keV	3×10^{16} – 3×10^{19}	0.01–10 nm	Scattering/diffraction from electrons	~0–15 Å, quantitative bond lengths and angles over short- and intermediate-range length scales
Neutron diffraction	0.1–500 meV	0.04–120 THz	0.04–3 nm	Scattering/diffraction from neutrons	~0–15 Å, quantitative bond lengths and angles over short- and intermediate-range length scales, dynamics
EXAFS	0.1–100 keV	3×10^{16} – 3×10^{19}	0.01–10 nm	Atom-specific absorption of X-rays, multiple scattering	~5–6 Å, quantitative atom-specific bond lengths and coordination
XANES	0.1–100 keV	3×10^{16} – 3×10^{19}	0.01–10 nm	Atom-specific electronic transitions to unoccupied orbitals, multiple scattering	~1–3 Å, qualitative coordination, oxidation state, electronic structure
XRS	Usually <10 keV	2.4×10^{13} – 3.4×10^{17}	~1–1000 nm	Energy loss of inelastically scattered X-ray photons	<i>In-situ</i> high-pressure energy loss spectra of low z elements (equivalent to XANES), short-range structure, electronic structure
XPS	~0.1–1400 eV	2.4×10^{13} – 3.4×10^{17}	~1–3000 nm	Energy of ejected core and valence electrons	Oxygen speciation (BO, NBO, free oxygen)
EELS/ELNES	10 meV–10 keV	7.2×10^{11} – 2.9×10^{17}	~1–1000 nm	Energy loss of transmitted electrons through the sample	Same as XANES
IR	886 meV–3eV	430×10^{12} – 300×10^9	1 mm–2500 nm	Molecular vibrations	Vibrational states, quantification of CO ₂ /H ₂ O in glasses, coordination states, short- and intermediate-range structure
Raman	1.2–120 meV	3×10^{11} – 1.5×10^{14}	0.5 mm–1000 nm	Molecular vibrations, inelastic photon interactions	Vibrational states, Q species, ring statistics, short- and intermediate-range structure
Brillouin	1.2×10^{-3} – 7.4×10^{-4} eV	10^7 – 1.8×10^{11}	100–1000 nm	Inelastic photon–phonon interactions	Elastic and acoustic properties
UV/Vis	1.7–124 eV	30×10^{19} – 790×10^{12}	10–700 nm	Valence electron transitions	Oxidation and coordination states of transition metals
NMR	12.4 peV–1.24 meV	3×10^3 – 300×10^9	~1 km–1 mm	Nuclear spin interactions	Short- and intermediate-range structure, bond angles, coordination states, Q species, dynamics
Mössbauer	100 keV	$>10^{19}$	<0.1 nm	Nuclear transitions	Oxidation state and coordination of Mössbauer active nuclei: typical Fe, Sn in glasses

In order to select the most suitable technique for probing the glass of interest, one has to determine what aspect of the structure is to be probed (bulk or atom specific), and what is the length scale to be probed (short-range, intermediate-range, or extended-range)? In many instances more than one technique will need to be employed. I will briefly discuss a number of common and not so common techniques for deriving structural information on glasses. Whereas space constraints limit the detail that can be provided, I will provide a general overview of what aspect of the structure is probed and what information can be determined from each method. The reader should refer to any of a number of detailed reviews of the specific techniques currently available (e.g. [1, 2]).

Acronyms

3Q	triple quantum
AFM	atomic force microscopy
AWAXS	anomalous wide angle X-ray scattering
BE	binding energy
BO	bridging oxygen
CN	coordination number
DAXS	diffraction anomalous X-ray scattering
EELS	electron energy-loss spectroscopy
ELNES	energy loss near-edge spectroscopy
eV	electron volt
EXAFS	extended X-ray absorption fine structure
FID	free induction decay
FSDP	first sharp diffraction peak
FT-IR	Fourier transform infrared
FWHM	full width at half maximum
HRTEM	high-resolution transmission electron microscopy
IR	infrared
IRO	intermediate-range order
IS	isomer shift
IVCT	intervalence charge transfer
keV	kilo electron volt
KK	Kramers–Krönig
LO	longitudinal optic
LRO	long-range order
MAS	magic angle spinning
MD	molecular dynamics
MQ	multiple quantum
NBO	non-bridging oxygen
NMR	nuclear magnetic resonance
NRIXS	non-resonant inelastic X-ray scattering
PDF	pair distribution function
PSF	partial structure factor
QS	quadrupole splitting
RDF	radial distribution function

RF	radio frequency
RMC	reverse Monte Carlo
SRO	short-range order
TO	transverse optic
TSF	total structure factor
UV	ultra violet
Vis	visible
XANES	X-ray absorption near-edge structure
XAS	X-ray absorption spectroscopy
XPS	X-ray photoelectron spectroscopy
XRS	X-ray Raman spectroscopy

2 Diffraction (Scattering)

2.1 X-ray and Neutron

Neutron and X-ray diffraction are two of the principal techniques used to probe the bulk structure of glasses through determination of average bond lengths, coordination numbers (CN), and angles over both the short (nearest neighbors) and intermediate (next-nearest neighbors) length scales. Data analysis and interpretation are comparable for X-ray and neutron diffraction so that I will differentiate between the two methods only when needed. In passing, note that in earlier studies the interaction between the X-rays and the sample was termed scattering, and not diffraction as made now.

For X-rays, diffraction experiments are readily made but they are not well suited to discriminate between neighbor atoms in the periodic table, such as silicon and aluminum, because of the similar electronic clouds with which X-rays interact in these cases. Thanks to their lack of electrical charge, neutrons are (with neutrinos) the only particles that can penetrate a condensed phase. They do not interact with electronic clouds, but are diffracted by atomic nuclei because they are strongly sensitive to nuclear forces. If both methods are available, the choice of X-ray or neutron diffraction depends to some extent on the chemical composition of the glass. Neutrons are, for instance, better suited than X-rays for investigating light elements such as H and they have the advantage of providing better spatial resolution and allowing more detailed information to be obtained through isotope substitution methods, which rely on the fact that neutron diffraction is sensitive to the neutron content of a nuclei. Practical factors have also to be taken into account: intense sources are much more widely available for X-rays than for neutrons, whereas the required sample sizes are of the order of 1 mg and 50 g, respectively. The samples themselves may be in the form of powders, glass chips, or shaped glass chips.

The “diffraction pattern” of a glass is very different from that of a crystal (cf. [3]). A crystal will produce a series of “spots” or “reflections” on a two-dimensional diffraction image or sharp diffraction lines on a powder diffraction trace. These cannot be seen in the diffraction image of a glass. This contrast is illustrated by the area electron-diffraction images of a crystalline material ($\text{Ba}_2\text{TiGe}_2\text{O}_8$, Ge-substituted fresnoite) and of an amorphous material ($\text{Ba}_2\text{TiSi}_2\text{O}_8$, fresnoite glass) shown in Figure 1a, b. Clearly, no “reflections” are observed in the glass image. A similar contrast is seen between an X-ray powder diffraction trace

of quartz (crystalline SiO_2) and that of the glass plate on which the quartz sample was mounted (Figure 1c, d). Note the very weak intensity, lack of diffraction peaks (reflections), and low signal-to-noise ratio of the glass trace. Where there is a “diffraction peak,” it has weak intensity and is extremely broad and diffuse, which is characteristic of a material lacking periodic structure.

Each reflection in a crystal image represents coherent diffraction from a plane of atoms whose intensity depends on the nature of these atoms. The “diffraction pattern” of a homogeneous glass will exhibit no such reflections but

Figure 1 Structural differences between crystals and glasses revealed by diffraction images and patterns. (a) Selected area electron diffraction image of crystalline $\text{Ba}_2\text{TiGe}_2\text{O}_8$ (fresnoite). (b) Similar image for $\text{Ba}_2\text{TiSi}_2\text{O}_8$ glass. (c, d) Powder diffraction traces for crystalline SiO_2 (quartz) and the glass slide on which the sample was mounted. Glass diffraction trace included in (c) to give an indication of the difference in intensity between a glass and a crystalline sample.

simply a series of diffuse rings or peaks reflecting those interatomic distances that prevail throughout the glass structure (Figure 1b, d). One does need to be aware that if the material is polycrystalline, it will also exhibit a series of rings but they will be better defined than those characteristic of glasses. Nevertheless, this type of diffraction image can be analyzed and interpreted to obtain average interatomic bond distances and angles, characteristic of the short-range order (SRO, nearest-neighbor distances), and to a lesser extent, the intermediate-range order (IRO). An example of SRO (typically up to ~ 3 Å) would be around a Si atom with the four oxygens of its SiO_4 tetrahedron, whereas IRO (typically up to ~ 3 – 5 Å) would be the linkage of this tetrahedron with others to form groups such as rings.

The most common information derived for glasses from the diffraction peaks shown in Figure 2 are radial distribution functions (RDF), which represent the probability of finding a given atom at any distance r from some atom considered to be at the center of the system. A RDF thus is a one-dimensional representation of the three-dimensional structure of a glass that is averaged over the entire system. Because these functions represent the sum of individual pair distributions for every atom of the material, they are widely used for comparisons with theoretical results to check the accuracy of the simulated glass structure.

If two theta (2θ) is the angle between incident and scattered beams and λ the X-ray or neutron wavelength, the wave or scattering vector is $4\pi \sin \theta / \lambda$. It is denoted as Q in

Figure 2 Information drawn for GeO_2 glass from diffraction data. (a) Measured total structure factor. (b) Total correlation function. (c) Pair-correlation functions showing the contribution from the individual atom pairs. Comparison with the earlier data of [4] is also shown. (Source: After [5].) Results corrected for a number of instrumental effects before derivation of pair distributions serving to identify the individual atomic pairs contributing to the bulk diffraction pattern of the sample.

neutron scattering, and as s or k in X-ray diffraction. In the latter case, it is common to extract the X-ray weighted Faber-Ziman or total structure factor (TSF), $S(k)$ [6], from the experimentally measured corrected coherent scattering intensity, $I_{\text{coh}}(k)$ (Figure 2a). The relationship between the TSF and $I_{\text{coh}}(k)$ is given by:

$$s(k) = 1 + \frac{I_{\text{coh}}(k) - \overline{|f|^2}}{|\overline{f}|^2}, \quad (1)$$

where $\overline{|f|^2} = \sum_i c_i f_i^2$ and $\overline{f} = \sum_i c_i f_i$. The RDF, $D(r)$, is then given by the Fourier transform of $S(k)$:

$$D(r) = \frac{2}{\pi} \int_0^\infty k [S(k) - 1] \sin(kr) dk. \quad (2)$$

The distribution function, $D(r) = 4\pi[\rho(r) - \rho_0]$, can be converted to the total pair-correlation function (Figure 2b). The TSF is the sum of the partial structure factors $S_{ij}(k)$ (PSF) for the different atoms i and j . The PSFs cause the oscillating contributions to the scattering curve and take the form:

$$S_{ij} = \frac{\sin kr_{ij}}{kr_{ij}},$$

where r_{ij} is the distance between atoms i and j . The TSF itself is expressed as:

$$S(k) = \sum_i^N \sum_j^N W_{ij} S_{ij}(k), \quad (3)$$

where $W_{ij} = c_i c_j f_i(k, E) f_j(k, E)$, C_i and C_j are the atomic fractions of species i and j , E the photon energy, and f_i and f_j the atomic scattering factors of species i and j . For GeO_2 glass, the measured TSF shows a first sharp diffraction peak (FSDP) at $1.5 \text{ \AA}^{-1}$ (Figure 2a left). From the total correlation function, i.e. the sum of all atom pair correlations (Figure 2b), one can extract (Figure 2c) partial pair-correlation functions showing the individual contributions to $G(r)$. For a binary compound such as GeO_2 , three PSFs are needed to obtain $S(k)$ (Figure 2c). These are $S_{\text{Ge-Ge}}$, $S_{\text{O-O}}$, and $S_{\text{Ge-O}}$, which correspond to contributions from Ge—Ge, O—O, and Ge—O bonds. The FSDP is characteristic of structural features in the IRO and longer length scales characteristic of long-range order (LRO). See Chapter 2.5 on the extended structure of glasses for a full discussion on the ordering ranges found in glasses.

Diffraction experiments provide information about the average structure of a glass. The positions of the peaks indicate interatomic distances, peak widths indicate bond distance variations, and the areas under the peaks are related to average CN. The RDFs have tall sharp peaks at small radial distances, but broad, low-intensity peaks at larger ones. This difference indicates that the structure is less variable at small (short-range) than at larger

(intermediate-range) radii. Consequently, the few first peaks in the correlation function can be assigned to well-defined interatomic distances whereas peaks at larger radial distance are less easily interpreted because they are composed of more than one atom pair correlation.

One can minimize the problem of overlapping contributions by collecting scattering data to higher k space to improve the resolution. One achieves this goal by using neutron scattering and collecting data out to $Q(k)$ ranges of $\sim 40\text{--}50 \text{ \AA}^{-1}$ or hard X-ray photons ($>40 \text{ keV}$) with wavelengths lower than 0.03 nm ($k \geq 30 \text{ \AA}^{-1}$). Furthermore, one can partly overcome the difficulty of interpreting peaks at high r values by using techniques that can separate the individual PSFs, such as anomalous X-ray scattering or isotope substitution. Currently, most glass diffraction experiments involve a combination of two or more techniques.

2.2 Isotope-substituted Neutron Diffraction

As already stated, this technique takes advantage of the dependence of the neutron diffraction on the number of neutrons contained in the atoms undergoing diffraction. By making isotopic substitutions in the sample, it becomes possible to eliminate some PSF in the TSF. This makes determining the various pair-correlation functions simpler and can lead to unambiguous assignment of features in the total correlation function to specific atom interactions. Basically, two experiments are performed on a sample in which one of the elements is in two different isotopic states. The two TSF can then be subtracted and their difference enables extraction of the PSF involving the element in the different isotopic states. To extract three PSF from a binary system, one requires diffraction experiments on three samples that are identical in every respect, except for the isotopic compositions of one or both of the chemical species.

The difference function is essentially similar to X-ray absorption spectroscopy (XAS) but the accuracy of the diffraction data can be improved to higher distances and providing more accurate CN of the element of interest. One should note, however, that the structural role of the two isotopes should be identical, which may not necessarily be the case as observed for light elements such as deuterium and hydrogen. The technique is similar to anomalous wide angle X-ray scattering (AWAXS) or diffraction anomalous X-ray scattering (DAXS).

2.3 DAXS and AWAXS

In these techniques, one determines the individual contributions to the TSF by each of the scattering atom pairs by using sharp changes in the X-ray scattering factor of an element near its X-ray absorption edge. The data are

qualitatively similar to those of extended X-ray absorption fine structure spectroscopy (EXAFS), but also include low- k contributions that contain information on the intermediate-range structure. Scattering data are collected at two or more different energies, one of them being close to the X-ray absorption edge of the element of interest. With AWAXS and DAXS, the idea is to cancel the correlations that do not involve the element of interest. This is also true for isotope-substituted diffraction.

3 X-ray Absorption Techniques

3.1 General Features

These atom-specific methods provide information on the structural environment of a specific element within a glass. The problem remains, however, that glasses are disordered and lack LRO so the data obtained are broadened relative to those for crystalline materials. Even though one may be looking at the structural environment of a single element, the data in addition represent the “averaged” structure over all the possible sites so that is very difficult to discriminate between distinct sites.

These methods provide similar information in spite of the different sources used for exciting the atomic interactions of interest. EXAFS or X-ray absorption fine structure spectroscopy (XAFS) along with X-ray absorption near-edge structure (XANES) spectroscopy constitute techniques that fall under XAS. EXAFS provides atom-specific quantitative data on bond distances, thermal bond-displacement parameters (i.e. Debye–Waller factors, σ), and CN. XANES can be used to determine qualitatively, the oxidation state, CN, and the electronic structure of the atom of interest. Both techniques are routinely carried out with synchrotron sources and dedicated XAS beam lines. Energy loss near-edge structure (ELNES) spectroscopy or electron energy loss spectroscopy (EELS) provides information similar to XANES, but uses instead the electron beam of a high-resolution transmission-electron microscope and relies on the energy loss as electrons are transmitted through the sample. X-ray Raman spectroscopy (XRS) or non-resonant inelastic X-ray scattering (NRIXS) is a relatively new technique that also provides similar information to XANES but uses the momentum transfer of hard X-rays (~ 10 keV) to induce the atomic interactions of interest. To date, XRS has been employed specifically to study elements *in-situ* at high pressure. Under these conditions, this is the only technique with which one can currently study elements in the soft X-ray range (< 2 keV), i.e. O, Si, Al, alkalis, and alkaline earths.

For all these techniques samples are usually powders (mgs) or glass chips (mm). For some experiments such

as transmission mode XAS experiments, however, care must be taken to ensure that the sample thickness is appropriate for the experimental conditions. If the sample is too thick, then self-absorption effects negate any useful data.

3.2 EXAFS and XANES

The closely related techniques EXAFS and XANES together constitute XAS. An XAS spectrum is divided into three regions: that of XANES, typically 0–50 eV above the X-ray absorption edge; of EXAFS or XAFS, typically ~ 50 – 1500 eV above the X-ray edge; and of the pre-edge ~ 20 – 30 eV below the edge (Figure 3). Both EXAFS and XANES are element-specific and potentially can be obtained from any element in the periodic table down to concentrations that can be as low as ~ 100 ppm.

EXAFS data are used for determining quantitatively bond distances, CN, the nature of the atoms surrounding the central atom of interest, and Debye–Waller factors. As illustrated for GeO_2 glass, the EXAFS portion of an XAS spectrum may be background corrected, normalized to 1 (Figure 4a), and then converted to k -space (reciprocal space) to get what is termed the $\chi(k)$ spectrum (Figure 4b). Part of this $\chi(k)$ spectrum is then Fourier transformed back into real space (R -space). The magnitude of the Fourier transform is essentially an RDF made up of the different atom pairs contributing to the $\chi(k)$ spectrum (Figure 4c), which is similar to the X-ray RDF. The first peak represents the Ge–O distances whereas peaks at higher R are due to multiple scattering and/or Ge–Ge, second Ge–O distances, etc. Modeling of the data (in R - or k -space) with reference to a crystalline

Figure 3 Typical information drawn from XAS spectra: processes causing the features observed in each energy range of interest. Spectrum of SiO_2 glass taken as an example.

Figure 4 EXAFS portion of the XAS spectrum of GeO₂ glass. (a) Background corrected and normalized to 1. (b) Converted to k -space (reciprocal space) for derivation of the $\chi(k)$ spectrum. (c) Magnitude of the Fourier transformed $\chi(k)$ spectrum, essentially a radial distribution function made up of the different atom pairs contributing to the source $\chi(k)$ spectrum.

standard (e.g. trigonal GeO₂ in this example) is necessary to extract the real interatomic distance. Without such modeling the interatomic distances are not accurate, being generally shorter than the real ones by $\sim 0.5 \text{ \AA}$.

The information drawn from XANES (Figure 5) on the electronic structure, oxidation state, CN, and nature of the bonding within the glass is more qualitative. This limitation is illustrated by the XANES spectra of Figure 5a where fewer and broader features are observed for SiO₂ glass than for quartz. Each peak represents an electronic transition of the Si 1s electrons to 2p states mixed with unoccupied oxygen states (orbitals). Comparison of the experimental XANES with first-principles calculations greatly facilitates detailed analysis of the electronic states.

One can also use XANES to determine the relative fractions of the different phases that are present in a mixture of crystalline materials. For this purpose, it suffices to perform a linear combination analysis whereby spectra of

crystalline standards are summed together in different ratios and compared with the experimental spectrum.

Of particular interest in glass science is the oxidation state and coordination of transition metal (TM) elements. For these elements, one predominantly uses the pre-edge features of the K -edge XAS, which represent excitation of a 1s electron to a 2p state (Figure 5b). These pre-edge features arise from formerly spin-forbidden electronic transitions that become “allowed” through site distortion. For some Ti-bearing crystals, the pre-edge shown in Figure 5b may contain from 1 to 3 peaks whose intensity is highest for the second or middle peak (fourfold coordinated Ti) and decreases with increasing Ti coordination (cf. [8, 9]). For iron (Fe) there can be two to three pre-edge features whose actual number and relative intensities depend upon whether or not there is Fe²⁺ and/or Fe³⁺, as well as upon the coordination geometries fourfold (tetrahedral or square planar), fivefold (trigonal bipyramid,

Figure 5 Information drawn from XANES data. (a) Fourfold coordination of Si in SiO_2 glass and quartz, and ordering contrast between the two phases. square pyramid), sixfold (octahedral), or higher coordination (eightfold, etc.) of the different oxidation states.

Fits to the pre-edge features can be made to extract the positions and intensities of the different contributions. Interpretation of the data requires a comparison of both the peak positions and intensities for accurate results (see [7]). Once determined, these parameters can be used in comparison with crystalline standards to determine likely coordination and oxidation states in the glass.

In XANES experiments the L -edge of transition metals can also be used for qualitative determination of oxidation state and coordination. But this edge is inherently more difficult to interpret because it originates in excitations (of a $2p$ electron principally to $3d$ or higher states) that are affected by spin-orbit coupling of the electrons. Analysis and interpretation of both K - and L -edge XANES spectra are greatly facilitated if one has access to first-principles calculations (simulations) of the edge of interest. Provided the partial densities of states (p-DOS) are yielded by the simulations, individual peaks can be assigned to interactions between specific unoccupied states (orbitals).

In addition, the position of the edge also depends upon coordination and oxidation state, moving to higher energies with increasing oxidation, whereas the overall shape of the XANES spectrum depends on the nature of the next-nearest neighbor interactions. Consequently, one

can use a “fingerprint” technique to compare the glass XANES spectrum with those of common crystalline analogues where the element of interest is in different coordination and/or oxidation states. This approach has been widely used to estimate qualitatively CN and oxidation states.

4 Nuclear Magnetic Resonance Spectroscopy

Electrons, protons, and neutrons all have spin quantum numbers of $\frac{1}{2}$ and can therefore interact with magnetic fields externally imposed or arising from nearby particles. Nuclear magnetic resonance (NMR) occurs when NMR-active nuclei in a magnetic field absorb and re-emit electromagnetic radiation at a specific resonance frequency. This frequency depends on the strength of the magnetic field and the magnetic properties of the nuclei of interest. The sample (~ 1 – 500 mg) is perturbed while in the magnetic field by a short radiofrequency (RF) pulse (usually 90° to the applied magnetic field), which releases the energy of the resonance transition measured as a free induction decay (FID) curve in the time domain. This curve is then Fourier transformed to the frequency domain to obtain the NMR spectrum. Because the FID

is very weak, usually multiple curves are collected and time-averaged. Also of importance is the time taken for the excited spin states to return to their equilibrium distributions; the *spin lattice* (T_1) or *longitudinal magnetic* relaxation, as well as the time for the FID to reach $1/e$ of its initial amplitude, the *spin-spin* (T_2) or *transverse* relaxation. The line width of an NMR signal is determined by T_2 (a long T_2 means sharper lines) and the maximum repetition rate during acquisition of an NMR signal is governed by T_1 (short T_1 means a spectrum can be acquired in less time). Additional information about the perturbed system can be obtained when one uses multiple and often complex RF pulse sequences and investigates the time and frequency dependence of the relaxation times. The reader should see [10] and references therein for a much more detailed description of solid-state NMR.

What makes this technique important is that the measured spin energies are affected by interactions with other electrons and nuclei in the sample and, consequently, by the local chemical environment around the element of interest. Furthermore, one can also probe the dynamics of these interactions on timescales of seconds to nanoseconds that makes its application to high-temperature studies particularly useful.

Although NMR spectroscopy is used to investigate site-specific information on elements with nonzero spin quantum numbers, it is most commonly carried out for elements whose numbers are $\frac{1}{2}$ or multiples of $\frac{1}{2}$ such

as $3/2$, $5/2$, $7/2$, and $9/2$. Little information can usually be drawn from the very broad NMR spectra of solids that result from the strong anisotropy of the NMR frequencies caused by variations in electron distributions. To reduce this broadening, the sample may be spun at an angle with the applied magnetic field resulting in what is termed magic angle spinning (MAS) NMR. Although MAS does not remove all the broadening effects, one can further reduce them by using multiple quantum (MQ) MAS NMR or (MQMAS) NMR for quadrupolar nuclei (those with spin quantum numbers $> \frac{1}{2}$). Triple quantum (3Q) is most common but 5 and 7Q can also be done. In the two-dimensional spectra recorded, one dimension is the equivalent of the MAS NMR spectrum and the other is the high-resolution isotropic dimension, which is thus free of anisotropic broadening but has peak positions shifted from the isotropic chemical shift as a result of the quadrupolar broadening (cf. Figure 6). A common use of MAS NMR spectra in glass science is to discriminate the coordination environment of a number of nuclides such as four-, five-, and sixfold Al, as illustrated in Figure 6a where the existence of distinct sites are revealed in Al-bearing sodium silicate glasses quenched from high pressure (6 GPa) [10].

Other factors can also broaden the signal such as unpaired electrons, which is why NMR is of limited usefulness in the presence of transition metals or magnetic rare earth elements in glasses although progress is being made to improve the situation. On the other hand, NMR

Figure 6 Structure determinations of sodium silicate glasses from ^{27}Al and ^{17}O 3Q MAS NMR spectra. (a) Aluminum coordination in samples quenches from 6 GPa. (b) Bridging oxygen linkages in the network. Source: Reproduced with permission from [10].

techniques have diversified so much in recent years to tackle such a wide variety of problems that it is impossible to summarize here these advances, or even to mention the technical terminology used by NMR experts. Rather, the reader is referred to the detailed discussion of NMR methods and applications given by Stebbins and Xue [10].

Some of the common elements studied in glasses are ^{31}P , ^{29}Si , ^{27}Al , ^{23}Na , ^{19}F , ^{11}B , ^{17}O , ^1H , and ^2H . The abundance of the NMR-active nuclide is important for determining the applicability of the technique. In some cases it is necessary to enrich the sample (usually powdered, although glass chips can also be used) with the appropriate nuclide if its natural abundance is low (e.g. ^{17}O). With appropriate nuclides, however, the sensitivity of NMR can be as low as 1% in crystalline materials and informative spectra can be collected for glasses and crystals with concentrations of the NMR nuclide well below 1%.

Typically, NMR spectroscopy provides element-specific information on short- and intermediate-range structure. The types of short-range information include coordination, Q speciation (Si tetrahedra with 1–4 bridging oxygens [BO] attached), and information on bond angles such as Si–O–Si. Intermediate-range information primarily deals with the type and nature of second neighbors, involving the connectivity of next-nearest neighbors and in some cases the connectivity of species out to fourth or higher nearest neighbors. In addition, NMR can provide dynamical information on timescales of ~ 0.1 to 1 ns and thus can investigate to some extent chemical kinetics and crystallization processes. As found with other spectroscopic techniques, NMR spectra are inherently broader for glasses than for crystals because of their intrinsically disordered nature. Double-resonance NMR methods can provide unique insights into distances between and interactions among multiple NMR-active nuclides, quite unique for NMR relative to other spectroscopies.

Spectra themselves are usually plotted as intensity versus a relative frequency scale plotted as parts per million (ppm). The frequency is reported relative to a standard and normalized by the excitation frequency:

$$\delta = 10^6 \left(\frac{\nu_{\text{sample}} - \nu_{\text{standard}}}{\nu_{\text{standard}}} \right). \quad (4)$$

The range of frequencies observed depends on the element being studied and sample composition. It is often referred to as the “chemical shift” although technically use of this term should be restricted to frequency shifts only affected by the chemical shift interaction. For ^{29}Si in glasses and minerals, it is usually in the range of -60 to -200 ppm. The chemical shift is sensitive to the coordination about the cation, higher coordinations giving rise to lower chemical shifts. Because the coordination is also strongly correlated with the cation–oxygen bond distance, the chemical shift generally decreases with

increasing bond length. At constant coordination the changes in chemical shift are much more subtle and may be partially overlapping. The chemical shifts of Q^n species (n = number of bridging oxygens) used to characterize SiO_4 tetrahedra, for instance, change by $\sim +10$ ppm with every decrease in n , and by $\sim +5$ ppm for every silicon nearest neighbor that is replaced by Al. In addition, the chemical shift depends on Si–O–Si and Si–O–Al angles, becoming more negative as the angles increase.

One of the most exciting nuclei has recently been ^{17}O NMR although the wide range of possible bonding environments for oxygen complicates interpretation of the spectra. However, ^{17}O NMR can be used to identify the cation neighbors to the non-bridging oxygens (NBOs), proportion of NBO vs BO, the coordination of the oxygens, and the nature of the cations around the NBOs. Consequently, the degree of order/disorder or mixing occurring between cations and different cation bonding environments can be resolved. For NaAlSiO_4 glass, the different BO linkages (Al–O–Al, Al–O–Si, Si–O–Si) in the network are, for instance, resolved in the ^{17}O 3QMAS NMR spectrum (Figure 6b).

5 Vibrational Spectroscopies

5.1 General Features

In the appropriate frequency ranges electromagnetic radiations can interact with the vibrational modes of a condensed phase whose energy depends on interatomic forces and on the geometry of the structural units involved. Specific structural units such as Q^n species thus have a characteristic vibrational signature whose changes as a function of chemical composition or temperature and pressure yields valuable structural information. With infrared (IR) and Raman spectroscopy, one probes in this way the interaction between atomic entities undergoing vibrational motion and an incident electromagnetic radiation whose energy is in the IR or visible regions of the spectrum. The difference between these techniques is that the interaction of the atoms and entities undergoing vibrational motion involves absorption and scattering of photons in IR spectroscopy and Raman spectroscopies, respectively, the energy of the incident photons varying by an amount (or a multiple of it) $E = h\nu = hc/\lambda$, where c is the speed of light, h Planck’s constant, ν and λ the frequency and wavelength of the vibrational mode probed. When recorded against the frequency of the light source, a spectrum thus shows a series of bands or peaks that are the fingerprints of specific vibrational modes. In contrast, Brillouin spectroscopy does not bring direct structural information because it relies on the interaction of photons with acoustic waves, which probes the bulk

and not some specific units of the substance. But it yields elastic coefficients, which themselves strongly depend on structure.

5.2 Infrared Spectroscopy

In IR spectroscopy the sample is illuminated by radiation from an IR source [11, 12]. The incident photons are absorbed if there is a change in the induced dipole moment of the bonds undergoing the vibration. This is due to the nonuniform distribution of charge along the bond. The IR radiation is measured as it is passed through (absorbed) or reflected by the sample. In general, molecules or molecular groups that have strong changes in their dipole moments (polar molecules and asymmetric vibrations) usually have strong IR spectra. Some vibrations can be observed by both IR and Raman spectroscopy whereas others may only be observed by one or the other and hence which technique is employed depends somewhat upon the types of vibrations that will be investigated.

IR spectroscopy is widely used to investigate water [13] and carbon dioxide in glasses [14], boron (B) coordination in borate glasses [15], and the structure of sol-gel derived glasses [16] and glass thin films. Kamitsos [12] has recently reviewed the application of IR spectroscopy to studies of glasses. The technique investigates the absorption or reflectance of IR radiation from the far ($\sim 10\text{--}400\text{ cm}^{-1}$) to mid-IR regions ($\sim 400\text{--}5000\text{ cm}^{-1}$). The samples can be powders (mg), glass chips (mm), or preferably glass chips where the surface of the chip has been polished. Older transmission studies often used glass powders mixed with some sort of matrix material (usually an alkali halide).

Studies on volatiles are carried out with IR absorbance techniques whereas IR reflectance methods are the most common for structural studies of glasses (especially borates) because in this case one does not need to correct for a number of spectral aberrations caused by a variety of sources such as, for example, variations in sample thickness. Reflectance spectra are transformed with the Kramers–Krönig (KK) transformation or via dispersion analysis to provide the optical and dielectric properties of the glass (cf. [12]). As in Raman spectroscopy, the observed peaks are generally characteristic of specific vibrational motions and molecular groups. In borate glasses (Figure 7) peaks at $800\text{--}1150\text{ cm}^{-1}$ are, for instance, due to B–O stretching vibrations of BO_4 tetrahedra whereas the bands at $1150\text{--}1550\text{ cm}^{-1}$ are indicative of stretching vibrations of B–O bonds in triangular borate units. The progressive changes in the $800\text{--}1550\text{ cm}^{-1}$ range observed in alkaline earth borates thus indicate a change in the B coordination from three to four when bond lengths and bond strengths change.

5.3 Raman Spectroscopy

Raman spectroscopy involves illuminating the sample with monochromatic light from a laser and observation of the photons that are scattered from the sample (see [17, 18] for a comprehensive discussion). The incident laser photons interact with the molecular vibrations or phonons in the sample and some of the incident photons gain or lose energy as a consequence of the interaction. This gain or loss in energy, observed as a change in frequency of the scattered photons, is called the Raman shift and results from inelastic interactions between the incident photons and the electron cloud around the vibrating atoms in the sample. When the electron cloud is deformed, a Raman shift will occur. This deformation is termed the polarizability of the molecule or bond. The Raman shift ($\Delta\nu$) is reported in terms of cm^{-1} , where $\Delta\nu = (\nu_0 - \nu_m)$, $\lambda_0 = 1/\nu_0$ is the laser wavelength, and ν_m the frequency of the Raman band.

Raman spectroscopy is widely used to investigate the structure of glasses and amorphous materials because it is sensitive to subtle structural changes that may occur in the glass network. It can thus be used to observe a number of short- and intermediate-range features. Its primary use is in investigating changes in the connectivity

and ring statistics of the glass network and the Q^n speciation in silicate glasses.

The Raman spectrum is characteristic of the material and can be used as a spectral signature to discriminate different types of glasses, and vibrations associated with specific structural features such as small and large rings, intermediate-range structure, BO and modifier vibrations, and NBO vibrations associated with differing Q species. The relative intensity of different vibrational bands is related to the concentration and nature of the vibrational source contributing to the band and can be used to obtain the relative concentrations of different molecular groups or structural entities. In some cases it is possible to obtain quantitative information through curve fitting of the Raman spectrum, although such measurements remain somewhat controversial. The samples are usually glass chips (mm) or polished glass surfaces similar to IR.

As examples, the Raman spectrum of silica glass and a series of sodium silicate glasses are shown in Figure 8. A number of Raman bands or peaks are observed whose positions depend on the type of atoms undergoing vibration and the nature of the vibration. Their intensities depend upon the degree of polarizability of the bonds and molecular groups involved. Heavier atoms exhibit bands at lower Raman shifts because the vibrational frequency in the classic harmonic approximation depends on both the bond force constant and masses of the atoms involved as exemplified by a diatomic molecule for which $\nu = \frac{1}{2\pi c} \sqrt{\frac{f}{\mu}}$ where $\mu = \frac{m_1 m_2}{m_1 + m_2}$, c is the speed of light, f is the bond force constant, and m_1 and m_2 are the masses of the two atoms undergoing vibration.

The Raman spectrum of SiO_2 glass can be used to aid interpretation of the Raman spectra of more complex

glasses. In the $10\text{--}200\text{ cm}^{-1}$ range is the Boson peak. This peak is characteristic of glasses and its origin remains controversial; it is accepted as being related to the extended- or intermediate-range structure. Its position and intensity depend to some extent on the degree of polymerization and distortion of the tetrahedral units making up the glass network [19]. Vibrations associated with BOs generally occur in the $200\text{--}850\text{ cm}^{-1}$ region of the spectrum. In silica glass there is a strong asymmetric band at $\sim 444\text{ cm}^{-1}$, two relatively sharp bands at ~ 490 and 606 cm^{-1} , and an asymmetric band at $\sim 800\text{ cm}^{-1}$. Two weak higher-frequency bands are also observed at ~ 1080 and $\sim 1200\text{ cm}^{-1}$. Both are due to BO vibrations associated with the SiO_4 tetrahedra. More specifically they are the T_2 and A_1 modes, respectively. The former involves in-phase stretching of the BOs toward and away from the central Si, the latter out-of-phase motion of pairs of BOs: one opposed pair moves toward the Si while the other moves away from the central Si. Through curve fitting the A_1 band has also been further subdivided into two components whose assignments remain controversial. The asymmetric 444 cm^{-1} band is due to symmetric stretching or rocking of the BO associated with rings containing more than 5 tetrahedra. Its position depends on the Si—O—Si angle, the peak maximum moving to higher frequencies with decreasing angle. The sharp 490 and 606 cm^{-1} bands represent oxygen breathing modes associated with relatively planar four- and three-membered rings of SiO_4 tetrahedra. They are often referred to as the D1 and D2 defect bands and are specific to silicate glasses.

The $\sim 800\text{ cm}^{-1}$ band is actually made up of two components at ~ 802 and 840 cm^{-1} and represents what is termed a transverse optic (TO)/longitudinal optic (LO)

Figure 8 Band assignments in Raman spectra. (a) In the unpolarized Raman spectrum of SiO_2 glass. (b) In a series of $\text{Na}_2\text{O-SiO}_2$ glasses (12–40 mol % Na_2O added, etc.), where the different Q species are observed with increasing Na_2O content.

split band. The splitting is caused by long-range Coulombic or electromagnetic forces. These components have been variously assigned to BO bending, symmetric stretching of the BO, and various “cage” motions involving Si and/or O. When assigning any Raman band, note that it is important that care be taken in fully understanding the nature of the vibration as different authors refer to similar vibrations with different terminologies: what may be a rocking motion in one paper could be symmetric stretch in another, both referring to the same peak and relative atomic displacements.

Intense bands in the 850–1300 cm^{-1} range are generally due to NBO symmetric stretching vibrations that are generated when network modifiers are present (cf., Figure 9). Usually different bands can be assigned to different Q^n species. A summary of the Q species distribution as a function of M_2O content where M = alkalis and the Raman frequency associated with each Q species are given in Figure 9. As the number of BOs (n) increases in a Q^n species, there is a shift of the NBO vibrational band to higher wavenumbers.

Each Q species has a vibrational band that occurs in a relatively distinct frequency range although this is not always clear as these ranges may overlap and some researchers have suggested the presence of two Q^3 or two Q^2 distinct species in some silicate glass compositions [20].

With the addition of other elements such as Fe, Ti, and P, a band is often observed around 900 cm^{-1} . This band is routinely assigned to vibrations associated with the added element, i.e. $^{[4]}Fe^{3+}$ —O vibrations. However, it occurs in a variety of different composition glasses and consequently

is more likely to be a vibrational band associated with the glass network that is generated as a consequence of the added element, rather than with vibrations specifically assigned to the element itself. Nevertheless, it can be used to quantify the amount of the element added to the system (cf. [15]).

5.4 Brillouin Spectroscopy

Brillouin spectroscopy is an optical technique used to investigate the elastic properties and acoustic velocities in glasses and melts under a variety of temperature and pressure conditions (cf. [21]). The method relies on inelastic scattering of monochromatic incident photons by thermal acoustic phonon vibrations in the sample. Whereas Raman spectroscopy investigates inelastic scattering between ~ 5 and 3500 cm^{-1} from an exciting laser, Brillouin spectroscopy measures the scattered light within 10^{-2} to <10 cm^{-1} (usually ± 1 – 2 cm^{-1}) of the laser line with a resolution of 10^{-3} cm^{-1} . Measurements can be made with two different kinds of sample geometries. With the so-called platelet geometry, the incident and scattered beams make the same angle θ with the normal to the in and out surfaces. One then derives the sound velocity from the relation

$$v_{s,p} = \frac{\lambda c \Delta\sigma}{2 \sin(\theta/2)}, \quad (5)$$

where $v_{s,p}$ is the sound velocity; λ and c the wavelength and velocity of light, respectively; $\Delta\sigma$ the observed Brillouin shift; and θ the angle between incident and the scattered light. Experiments made with the backscattering geometry are simpler to perform as they require only a polished surface, but the index of refraction then needs to be known independently to determine the elastic properties.

The spectra consist of peak doublets on either side of the laser line frequency. The position, intensity, full width at half maximum (FWHM), and polarization of the peaks give information on the acoustic velocities and viscoelastic properties, coupling coefficients (between fluctuations and the electromagnetic field), the lifetime of the interactions and the anisotropy of the interaction, respectively. Thus, one can use changes in acoustic velocities, for example, to infer the occurrence of polymorphism/polymorphism at high pressures in glasses such as SiO_2 (e.g. [22]). Figure 10 shows a number of spectra for an anorthite composition ($\text{CaAl}_2\text{Si}_2\text{O}_8$) glass at various pressures. Note the structural change between 5.4 and 7.2 GPa (*indicates peaks due to the pressure transmitting medium) indicated by the shift in the peak at $\sim \pm 40$ GHz. The elastic line region is the exciting laser line and notch filter cutoff.

6 Other Techniques

In addition to the common methods discussed above (Sections 2.1–5.4), a number of other techniques can be used to probe more specific structural features.

6.1 Mössbauer Spectroscopy

This extremely sensitive technique relies on the recoil-free resonant absorption and emission of gamma rays in solids (Mössbauer effect). It probes small changes in energy levels associated with the nucleus. However, only a relatively limited number of elements are suitable for study. This is because Mössbauer spectroscopy relies on the radioactive decay of a parent isotope to that of interest, which has a sufficiently long half-life to make real-time experiments realistic. In glasses, the most common elements exhibiting this effect are iron (^{57}Fe) and tin (^{119}Sn), the radioactive sources being ^{57}Co and usually $^{119\text{m}}\text{Sn}$, respectively (cf. [23]). The samples are usually powders (mg) that are mixed with some sort of inert matrix such as sucrose in order to dilute the concentration of the Fe or Sn. If the Fe or Sn concentration is too high, a useful Mössbauer spectrum will not be obtained. One can determine the oxidation state and coordination of Fe in glasses based on the analysis of the isomer shift (IS) and quadrupole splitting (QS) values extracted from Fe Mössbauer spectra. The spectra of iron-containing glasses generally exhibit an asymmetric doublet whose full width at half maximum are larger than those of crystalline materials. A number of different models are usually fitted to the doublet (Figure 11). In early studies sets of symmetric Lorentzian curves were used to represent the different potential Fe sites but in more recent years fits of the quadrupolar splitting or hyperfine

field distributions are usually preferred. Typical IS (δ) values for silicate glasses fall between 0.20 and 0.32 mm/s for Fe^{3+} in tetrahedral coordination, 0.35–0.55 mm/s for Fe^{3+} in octahedral coordination, 0.80–0.95 mm/s for Fe^{2+} in tetrahedral coordination, and 1.05–1.55 mm/s for Fe^{2+} in octahedral coordination. The presence of fivefold Fe has been observed in glasses with IS and QS values lying between those of four- and sixfold Fe. However, it is difficult to distinguish Fe in fivefold coordination from a mixture of Fe in four- and sixfold coordination.

Tin spectra are usually broad (FWHM ~ 1 mm/s) symmetric doublets. For Sn^{4+} , QS values are small and the IS is close to 0 mm/s whereas Sn^{2+} has IS and QS values of 1–2 and 2–3 mm/s, respectively. For Sn^{2+} , the IS is more negative for tetrahedral than for octahedral sites.

6.2 X-ray Photoelectron Spectroscopy

Although it has been widely used to study the surfaces of materials (see [24]), X-ray photoelectron spectroscopy (XPS) can also provide information on the bulk structure. Its application to glasses has been relatively limited to date but it can determine quantitatively the NBO and BO concentrations as well as the concentration of free oxygen (O^{2-}), the oxygens not bound to a network former. The technique measures the kinetic energy of photoelectrons that are ejected from the sample (a mm-glass chip with a freshly exposed surface) as a result of ionization of an element by an incident X-ray beam. The kinetic energy of the photoelectron can be simply related to the binding energy (BE) of the electron to the nucleus so that it is characteristic of both the element from which it has been ejected and the environment around the element. One can scan for the

Figure 11 Contributions of Fe^{2+} (light gray) and Fe^{3+} (dark gray) to the Mössbauer spectrum of a Fe-containing borosilicate glass as determined from fits made with 2-d Gaussian distributions [15].

presence of specific elements and obtain high-resolution spectra of well-resolved energy ranges. The concentration of the different oxygen species are determined by curve fitting of the O 1s XPS spectrum [25]. The BO BE is at higher energy ($\Delta \sim 1.4$ eV) than the NBO peak but their FWHM are comparable (average ~ 1.22 eV). The free oxygen peak is incorporated into that of the NBO to the low-energy side and is observed as an increase in the FWHM of the NBO peak. This is shown in Figure 12 for a PbO-SiO_2 glass. The NBO peak has two contributions, one from the NBOs and one from the presence of free oxygen (O^{2-}), also called non-network oxygen.

6.3 Ultra Violet/Visible Spectroscopy

The absorption, reflection, or emission of light in the near UV to near IR ($\sim 250\text{--}3000$ nm) is also a source of structural information. In UV/Vis spectroscopy, one thus measures the absorption of light by a material caused by a number of factors: electronic transitions of transition metal d electrons, intervalence charge transfer (IVCT) and anion–cation charge transfer, electronic transitions between the conduction and valence bands, vibrational overtones, electronic transitions between f-orbitals, defects, and electron holes [26]. The technique is primarily used to investigate the causes of color in glasses through the oxidation and coordination environment of coloring transition metal elements such as Ni within glasses (Chapter 6.2). In general, specific absorption bands are observed that are characteristic of the transition metal, its oxidation state, and coordination. The

Figure 12 The different oxygen species identified from the XPS O 1s spectrum of a lead silicate glass. BO peak is constrained to a linewidth of 1.22 eV and fitted with two peaks in the NBO envelope, one due to NBOs and the other to the presence of free oxygen. Glass made and spectrum obtained by Ryan Sawyer, University Western Ontario.

samples are usually polished glass chips (mm) or slabs (mm–cm). In addition, sample thickness may need to be adjusted for specific experimental conditions.

7 Perspectives

In this chapter I have by no means covered all the possible methods that can be used to investigate the structure of glasses. In addition to variations in many of the specific techniques covered in this chapter, many more techniques including imaging methods such as atomic force microscopy (AFM) and high-resolution transmission electron microscopy (HRTEM) can be used (Chapter 2.3). Whereas the ability to “solve” the structure as done in crystal-structure analysis is not possible, our ability to probe the structure of glasses has greatly improved since the first studies in the early decades of the twentieth century. Progress in X-ray and neutron sources, lasers, detector sensitivity and resolution, and computers have all contributed to improve greatly the resolution and length scales observable in glasses and other amorphous materials.

Unlike for crystalline materials, however, any structural study of a glass must involve a multi-technique approach since no single method can supply information on all aspects of the structure. In addition, it is advantageous to use numerical techniques such as simulations of spectra, first-principles molecular dynamics (MD) simulations, and reverse Monte Carlo (RMC) calculations to aid interpretation of the experimental data. While our understanding of the SRO continues to improve, that of the IRO and LRO remains murky, as is the link between structure and, physical properties and behavior, as well as, structural changes that occur with increasing pressure and temperature. With continued advances in experimental instrumentation and computational methodologies, the outlook for resolving many of these structural issues is good.

Microstructure Analysis of Glasses and Glass Ceramics

Christian Patzig and Thomas Höche

Fraunhofer Institute for Microstructure of Materials and Systems IMWS, Halle (Saale), Germany

1 Introduction

A homogeneous glass by definition lacks a microstructure at a scale larger than a few nanometers. As soon as actual inhomogeneities occur, in contrast, a detailed picture of their size, distribution, composition, and spatial arrangement becomes important to understand the properties of the material. In turn, the improved capabilities of microstructural studies in terms of spatial and elemental resolution are becoming increasingly important to optimize crystallization or phase separation and to achieve the desired microstructure and associated properties (Chapter 7.11). As a matter of fact, the beauty and challenge of glasses and glass ceramics is their diversity and complexity.

The purpose of this chapter thus is to review the main microstructural methods commonly used to study inhomogeneous glass-based materials. In preamble, however, it is important to note that studying extremely small volumes in great detail can result in “knowing everything about nothing.” In other words, it is critically important to make sure that the information gathered locally is actually representative for larger volumes. To achieve this goal, highly resolved information must be combined with additional integral measurements to get a broad picture. In addition, artifacts introduced upon either preparation or investigation of the sample must be avoided. And one should also be extremely careful with *in situ* microstructural experiments where, because of dramatic differences in the surface-to-volume ratio, annealing can easily lead to results not observed in the bulk. For this reason, one is advised to freeze a microstructure evolution by stopping

it at specific steps and to use multiple samples taken from different stages for gaining a “full-picture” characterization.

When dealing with the early stages of crystallization or nanoscale phase separation, it is obvious that light microscopy is not an appropriate analysis technique because its optical resolution of a few 100 nm, which is limited by the wavelengths of visible light, is two orders of magnitude too low. Fortunately, however, there are various ways to improve spatial resolution. As described in Chapter 2.2, the first is to probe the material with photons of shorter wavelengths such as X-rays: at 154 pm, the wavelength of Cu- K_α X-rays is for instance 1000 times shorter than that of visible light. A second way is to take advantage of the wave-particle dualism of electrons or ions. Under accelerating voltages of 25 and 200 kV, the electron wavelengths are even shorter than that of typical X-rays, with values of 8 and 2.5 pm, respectively. As a matter of fact, the former value is typical for studies of sample surfaces by scanning electron microscopy (SEM), whereas the latter applies to investigations by transmission electron microscopy (TEM) of bulk samples with a thickness of a few tens of nanometers at most, to limit electron absorption. In addition to these two techniques, to which we will pay particular attention, the third way to achieve high resolution will also be described. It relies on the use of scanning probes whereby a needle that is atomically sharp at its end is moved over the sample surface by a piezo drive that must be highly precise, since the key to resolution is, in this case, the accuracy of the needle position.

In practice, the formation of a given microstructure can be extremely complicated, including secondary, ternary, or even quaternary phase separation or the nucleation of multiple functional phases on finely dispersed seed crystals [1, 2]. Rather than trying to document all such processes, we prefer to illustrate the capabilities and complementarity of the methods described in this chapter

Reviewers: C. Bocker, Friedrich-Schiller-Universität Jena, Jena, Germany

with a single glass ceramics whose starting composition (in mol %) is $50.6 \text{ SiO}_2 \cdot 20.7 \text{ MgO} \cdot 20.7 \text{ Al}_2\text{O}_3 \cdot 5.6 \text{ ZrO}_2 \cdot 2.5 \text{ Y}_2\text{O}_3$, whence its MAS acronym from its main components MgO , Al_2O_3 , and SiO_2 . Under an appropriate temperature and time treatment, this glass transforms to a glass ceramics whose microstructure shows a variety of features with which the pros and cons of the most common techniques are nicely illustrated [3–17]. And this glass ceramics also illustrates how a specific material property can be explained only in microstructural terms: in this instance an unusually high bending strength exemplifies differential expansion strengthening (Chapter 3.12) resulting from precipitation of ZrO_2 (zirconia) and MgAl_2O_4 (spinel), two crystals with high thermal expansion coefficients, in a glassy matrix of lower expansivity.

Acronyms

AFM	atomic force microscopy
BSE	backscattered electron(s)
CL	cathodoluminescence
EDXS	energy-dispersive X-ray spectroscopy
EELS	electron energy loss spectroscopy
FIB	focused ion beam
HAADF	high-angle annular dark field (imaging)
MAS	magnesium aluminosilicate (glass ceramics)
SAED	selected area electron diffraction
SE	secondary electron(s)
SEM	scanning electron microscopy
STEM	scanning transmission electron microscopy
TEM	transmission electron microscopy
XRM	X-ray microscopy
WDXS	wavelength-dispersive X-ray spectroscopy

2 Scanning Electron Microscopy

2.1 Image Formation

In SEM a finely focused primary electron beam possessing an energy in the 100 eV–30 keV range impinges onto the surface of a sample placed in vacuum (Figure 1). By interacting with the sample atoms, electrons generate many different signals. If the primary electron beam is scanned across the surface, an image can be formed not only from secondary electrons (SE) but also from backscattered primary electrons (BSE) and cathodoluminescence (CL). In addition, the chemical composition of the sample surface can be determined from the generated X-rays and Auger electrons.

The primary beam diameter can be as small as a few nanometers, but the magnification is determined by the distance between the positions of the beam successively held to acquire one of the secondary signals and to generate an intensity signal in the digital image derived. Well below the sample surface exposed to the scanning electron beam, however, even the smallest primary beam undergoes some scattering upon interaction with the atoms in the bulk of the sample. Channeling effects may also occur if the sample is fully or partly crystalline, i.e. electrons may penetrate more deeply into some areas of the sample before scattering if a specific crystallographic orientation is well aligned with the direction of the electron beam. The spatial resolution of an SEM micrograph is, therefore, rather determined by the interaction volume (with typical extensions of several 100 nm in width and depth beneath the surface; cf. Figure 1) than by the initial spot size of the beam.

Depending on the type of (secondary) signal used for imaging and analyzing the sample, the depth of information and, accordingly, the lateral resolution as well will be very different. For instance, SE have energies lower than

Figure 1 Interaction volume and main secondary signals occurring when a primary electron impinges on a sample surface.

about 50 eV. Those that leave the sample surface can thus reach the detector system only if they stem from the “neck” of the excitation volume, i.e. down to approximately 50 nm beneath the surface. The SE generated at greater depths do not reach the surface to leave the sample because of self-absorption effects resulting from their rather low energy. On the contrary, the highly energetic backscattered electrons (BSE) – as well as the X-rays used for chemical analysis – may also stem from the “bulk” of the excitation volume, further below the sample surface down to some 100 nm. This interaction volume strongly depends on experimental factors that can be adjusted to some extent. For instance, reducing the acceleration voltage reduces the sample penetration depth and, thus, the size of the resolution-determining excitation volume. It may also help to increase the resolution by reduction of sample charging, a problem that is always encountered when nonconducting samples (like most glasses) are analyzed.

Such adjustments, however, might worsen other aspects of the experiment. When probing the sample composition from the energy of the characteristic X-rays emitted, the primary electron beam should, for instance, have an energy that is high enough to generate these X-rays. In other words, an acceleration voltage amounting at least to twice the X-ray energy to be excited is needed, in spite of its ensuing implications on interaction volume, charging, and also sample degradation. In summary, one should always think first about the intended experiment – the crucial information to be gained – and adjust the experimental conditions accordingly.

An advantage of SEM is that sample preparation is simple. Glasses and glass ceramics are typically just ground and polished. More specific techniques rely on wet-chemical etching to generate a topography related to the differing dissolution rates of the constituents of the microstructure (e.g. the vitreous “matrix” vs. crystalline precipitates) and on focused ion beam (FIB) etching to get access to regions buried under the surface.

When glasses are electric insulators, care must be taken to avoid accumulation of electrical charges on the surface, which could influence image formation by deflecting ingoing or outgoing electrons, particularly those that possess only low energies. Coating the sample with a few nanometers of carbon helps drain away such charges, but potentially covers fine details of the microstructure and adds a local source of contamination by carbon redistribution on the surface. Another way to prevent charging is imaging under poor vacuum conditions. This is done in so-called environmental or vapor-pressure SEMs, where a certain partial pressure of, for example, water vapor is maintained above the sample surface, whereas a pressure gradient ensures that the electron-emitting source is kept in ultrahigh vacuum. In this experimental setup, primary

electrons ionize water molecules that eventually neutralize charges on the sample surface. Last but not least, the total electron yield (SE and BSE leaving the sample) depends on the acceleration voltage. Provided that this voltage can be properly varied, conditions can be found such that as many electrons enter the sample as leave it, resulting in the absence of charging. Typically, such conditions are encountered for acceleration voltages of only a few 100 V. Whereas imaging resolution is improved in this way, the disadvantages include an enhanced susceptibility toward contamination of the scan field as well as a practical inability to perform X-ray spectrometry because the electron energy will be insufficient to induce X-ray emission from the sample.

2.2 Chemical Analyses

Characteristic X-rays excited by high-energy electrons can be recorded either by energy-dispersive X-ray spectroscopy (EDXS) or by wavelength-dispersive X-ray spectroscopy (WDXS). Stemming from electronic recombination, the X-rays generated fingerprint the electronic structure of the excited element, thus making quantitative analyses possible. Soft X-rays (e.g. emitted by light elements) are subject to absorption on their way out of the sample, however, so with decreasing atomic number, the emission of Auger electrons counteracts that of X-rays. Hence, quantification for elements with atomic numbers smaller than 13 requires extraordinary diligence.

In EDXS, a semiconductor detector is used to count electron-hole pairs generated by the impinging X-rays. The spectral resolution is typically on the order of 130 eV, so in a few cases overlapping emission lines cannot be clearly separated: this will, for instance, apply to the $\text{Ti } K_{\alpha 1}$ and $\text{Ba } L_{\alpha 1}$ at about 4.51 and 4.47 keV, respectively. This problem is less serious with WDXS (with a spectral resolution of ≈ 10 eV), where Bragg’s law of selective reflection forms the basis of detection in a proportional counter. Whereas EDXS is a parallel-registering technique, WDXS (which is very similar to electron microprobe analysis [EMPA]) is a serial technique, making it more time consuming and less commonly used than EDXS.

For a sufficient yield of X-rays of a certain energy, as a rule of thumb, the primary electrons should have a kinetic energy of at least twice that amount. As an example, $\text{Si-}K_{\alpha}$ X-rays possess an energy of 1.74 keV, which is similar to the difference between the $\text{Si-}K$ and the $\text{Si-}L_{2,3}$ energy levels in the electron shell of the Si atom. Thus, one needs to use at least 3.5 kV acceleration voltage to be able to detect Si in a glassy sample by means of EDXS or WDXS, let alone any heavier elements. Low-voltage excitation in

SEM might thus be advisable for imaging purposes, but not for chemical analysis.

2.3 Application to Glass Ceramics

To illustrate the information depth one can gain with that technique, the aforementioned MAS glass ceramics will be selected. In this sample, precipitation of zirconia and spinel is known from X-ray diffraction (XRD) experiments, but this technique is inappropriate for investigating the micro- and nanostructure because it gives information about the sample as a whole, with a low spatial resolution defined by the X-ray spot size. Techniques such as SEM or TEM must be used instead, and they can in addition yield the composition of the residual glass and the structure of the crystals – in this case whether zirconia is the tetragonal, cubic, or monoclinic polymorph.

For a piece of this MAS sample, polished and rendered conductive by deposition of a $\approx 3\text{--}5\text{ nm}$ carbon film on its surface, an SEM micrograph (SE) taken with an acceleration voltage of 10 kV clearly shows bright, elongated

structures and areas with brighter and darker appearance (Figure 2a). A comparison with an SEM micrograph acquired at a 30 kV acceleration voltage (Figure 2b) illustrates the loss of both resolution and contrast when the energy of the primary electrons increases and results in deeper electron penetration in the bulk. In turn, the effect makes the origin of the image-forming SE less predictable, so fine details are smeared out at the surface of the sample. At a higher magnification (Figure 2c), the microstructure observed with a 10 kV acceleration voltage from backscattered primary electrons (BSE) shows the dendritic appearance of the brightest, elongated features that indicate their crystalline nature. Resulting from strong scattering of the primary electrons, the marked contrast of these features with their surrounding suggests the presence of heavy elements (and associated high backscattering yield). Given that zirconia is present in the sample and that the other heavy element besides zirconium, i.e. Y, is not expected to enter another crystalline phase in this material, one can conclude that the bright dendritic microstructure is likely made up of zirconia.

Figure 2 Scanning electron micrographs of the MAS glass-ceramic sample: resolution differences between 10 kV (a) and 30 kV (b) acceleration voltages and BSE micrograph taken at 10 kV at higher magnification (c) showing the bright (1) and dark (2) areas for which the EDX spectra of (d) were acquired.

Around the dendrites, the brighter and darker areas should then be the images of the spinel and the residual glass, respectively.

To check this conclusion, EDXS analyses were made in the two areas indicated in Figure 2c. The spectra are presented in Figure 2d. In both, a small carbon peak is an artifact of the sample preparation. Besides the most intense oxygen and silicon peaks, the other peaks are readily assigned to the other elements, but a clear separation of the $Y-L_{\beta}$ and $Zr-L_{\alpha}$ peaks is not possible owing to the limited energy resolution of the EDX detector system. The better separated $Y-K$ (at ≈ 14.9 keV) and $Zr-K$ lines (at ≈ 15.7 keV) would be more suitable, but a higher acceleration voltage would be needed to access that higher-energy part of the EDX spectrum with its ensuing loss of image resolution.

Nevertheless, these EDX spectra suggest that the brighter areas likely are silica rich, most probably depicting the residual Y-bearing glass. Conversely, the darker areas should consist of spinel, which is Si- and Y-free, as confirmed by analyses made in the “darker” area of the sample where O, Al, and Mg are found with a higher Al/Si ratio than in the other spectrum. The reason why certain amounts of Si and also of Zr (but not of Y) are nonetheless detected is that a certain interaction volume is also excited below the surface within the sample (cf. Figure 1). As a result, the lateral resolution is worsened, and the probed area does not include only the “dark” region 1 that is visible in Figure 2c, yet also parts of the sample bulk below. In conclusion, like any technique, SEM and EDXS have their own limitations. Other methods having a higher resolving power must be used to overcome them.

3 Transmission Electron Microscopy

3.1 Conventional Observations

Analytical (scanning) transmission electron microscopy [(S)TEM], currently is the best method for both imaging and determining chemical compositions [18] whenever the relatively large excitation volume of SEM becomes problematic. The price to be paid is the necessity to prepare samples as thin as a few 10 nm, without preparation artifacts, to make them transparent to electrons. The task is difficult, but over the years a wide range of techniques have been developed for this purpose, including mechanical grinding, ion beam etching, preparation of replica, ultramicrotomy, and FIB machining of lift-out TEM lamellae [19]. In this respect one should distinguish between samples taken from the bulk and cross-sectional samples cut out from specifically targeted areas (e.g. if a specific source of devitrification in a glass has to be

assessed for further analysis) for which FIB machining is particularly well suited.

In its principle, a transmission electron microscope is amazingly similar to a light microscope: the electron source corresponds to the lamp; beams are formed by electromagnetic lenses (which are true zoom lenses as one can finely change their focal length by altering the lens current); image and object planes are defined; and after converting the electron distribution into light with a scintillator, an image is formed and registered by a CCD or CMOS camera. Of course, however, TEM offers a number of tremendous advantages over light microscopy that result from the much lower wavelengths of electrons compared with those of visible light. First and foremost, it has a much higher spatial resolution, as the best commercially available instruments can now resolve lattice planes as close as 50 pm apart [20]. Second, unlike for optical lenses, the focal lengths of electron lenses can be changed during operation, allowing for switching between parallel illumination and formation of a focus spot of less than 100 pm in diameter for dedicated analyses of very small sample regions. Third, one can switch between imaging and diffraction modes, which makes it possible to identify crystalline phases from the recorded electron diffraction patterns. Fourth, the higher energy of electrons (as compared with visible light) allows electronic transitions to be excited, laying the ground not only for analyzing chemical compositions (EDXS) but also for assessing the coordination and valence of appropriate elements (electron energy loss spectroscopy [EELS] [21]).

In conventional TEM, the sample is illuminated with a parallel beam. Bright- or dark-field micrographs are recorded depending on whether or not one includes in the image formed the primary (central) beam in the diffraction plane, which is the back focal plane (Figure 3). Contrast, i.e. the visibility of objects, in bright-field imaging is simply explained: if a certain area scatters (inelastically) or diffracts (elastically) more strongly than its surroundings, the electrons passing through this area will be deflected to higher angles than the non-scattered or less scattered/diffracted electrons. By introducing a contrast aperture (the objective aperture in Figure 3), one blocks electrons traveling far from the optical axis. As a consequence, the corresponding areas in the micrograph appear less bright.

For glasses and glass ceramics, microstructures typically generate various kinds of contrasts. In liquid–liquid phase separation, droplets containing elements heavier than those of the surrounding matrix appear as less bright regions on micrographs (although atomic number differences can be so small as to make phase-separated droplets hardly discernable). Crystalline precipitates always appear much darker than their glassy

Figure 3 Electron beam paths in the parallel sample illumination mode in TEM. Left: direct beam used for imaging (bright-field imaging technique). Right: diffracted beam used for imaging (dark-field imaging technique). In both cases one selects the appropriate beam by moving the objective aperture in the back focal plane (diffraction plane).

surroundings for two reasons: First, crystal lattices induce strong diffraction up to high angles, particularly when they are well aligned along a low-index crystallographic axis. Second, when these precipitates preferentially incorporate heavy elements, their cross sections for inelastic scattering are also larger than those of their glass surroundings. The effect is seen in Figure 4a for the bright-field TEM micrograph of a MAS glass ceramics similar to that discussed above for SEM (both from the same green glass, with just a different annealing such that only zirconia precipitated in that case).

As already mentioned, one can readily tune electron lenses to the desired focal length to image also the back focal (diffraction) plane. A well-oriented zirconia is revealed in this way in the MAS glass-ceramic sample (Figure 4a). Information on circular areas of less than

200 nm in diameter can even be obtained with the so-called selected area electron diffraction (SAED) aperture as illustrated in Figure 4b for the MAS sample. Indexing of the pattern further shows that the ZrO_2 crystal is aligned along the [100] direction, which unambiguously indicates its tetragonal symmetry.

Dark-field and bright-field imaging are again closely related (Figures 3 and 4c) because a small contrast-enhancing aperture can also be positioned in the diffraction plane of the objective lens in such a way that the direct (undiffracted) beam is *not* allowed to pass through it. Originating either from crystal diffraction spots or from amorphous diffraction rings, some of the diffracted intensity is allowed instead to travel further down the microscope column and form an image. Because the relatively small apertures ($>5 \mu\text{m}$) are circular holes and not

Figure 4 Transmission electron micrographs of the MAS glass ceramics. (a) Bright-field image where crystalline ZrO_2 features appear dark in a glass matrix of bright contrast. (b) Electron diffraction pattern taken from a sample area circled in (a). (c) Dark-field TEM micrograph of the same sample area. Crystal appearing bright because the objective aperture is moved away from the direct beam to allow only diffracted beams to pass by. (d) Aberration-corrected high-resolution TEM micrograph of a part of the sample where a ZrO_2 crystal has a boundary with the surrounding glassy matrix.

annular rings, dark-field imaging always catches only a fraction of the diffracted intensity, resulting in much longer exposure times and associated risk of running into drift issues. Dark-field imaging is nevertheless often useful since its sensitivity to small differences in diffracting/scattering power is clearly superior to that of bright-field imaging. In addition, it often makes a “quick survey” possible for crystalline areas in the sample. As an example, the zirconia crystals embedded in the glassy MAS matrix appear as the bright area in the dark-field image of Figure 4c, where only significantly diffracted or scattered electrons contribute to the contrast with the dark surrounding glassy matrix.

With high-resolution TEM (HR-TEM), one can image directly rows of atoms in the crystalline parts of the specimen provided that the sample is thin enough and that crystallographic directions are well aligned with respect to the optical axis, which is accomplished by phase-contrast imaging. The physics involved will not be expounded here because it is beyond the scope of this chapter, but one can think of a crystalline specimen as a weak phase object analogous to a phase grating for visible light [18]. Interatomic potentials within the crystals then affect the wave functions of the incoming electrons so that one can extract from these modifications a picture of the atomic lattice of the crystal that is visualized on a fluorescent screen or captured with a CCD or CMOS

camera. The resolution that can be obtained is well below the nanometer range, as shown in Figure 4d where a sharp boundary separates the regular crystal lattice of zirconia from the disordered atomic arrangement of the glass matrix.

3.2 Scanning Transmission Electron Microscopy

As a complement to the wealth of information on micro- and nanostructure that can be obtained from parallel-illumination-based TEM observations, one can also perform chemical analysis with modern machines, for example, by means of EDXS. In order to do so, sample areas as small as possible should be assessed directly with a finely focused probe to achieve the best lateral resolution possible. That is where scanning transmission electron microscopy (STEM) comes into play. In STEM, the sample is not illuminated with a broad parallel electron beam. Instead, the condenser lens system is used to form a fine electron beam that can be moved laterally over the sample surface with the help of deflection coils, in close analogy to what is done in an SEM. The difference is that SE emitted from the sample upon electron impingement are not detected. The primary electron beam passing through the very thin specimen of course remains used for imaging, but it loses energy through interactions with the sample atoms by either elastic

(diffraction) or inelastic scattering. Of special interest for imaging are the inelastically scattered electrons, since the resulting contrast is highly sensitive to the mass of the atoms in the specimen. The scattering cross section of that electron–sample interaction approximately varies with the atomic number Z of the screened sample atoms according to Z^a , where a is in the 1.2–1.8 range [22]. Thus, the heavier or denser the analyzed sample position, the larger the scattering angle of the primary electrons.

Usually the setup for catching the scattered primary electrons consists of a ring-shaped detector below the sample (Figure 5). In this (high-angle) annular dark-field [(HA)

Figure 5 Working principle of the scanning transmission electron microscope.

ADF] imaging mode, the larger the scattering angle of the primary electrons, the more signal will be recorded on the detector. Thus, heavier elements in the sample generally appear as brighter features in the image. The camera length is the distance between the sample and the detector. Because one can change it easily by adjusting the electromagnetic lenses of the TEM, it is possible either to induce only Z-contrast in the image (short camera length) or to use a fraction of the elastically scattered (diffracted) electrons to gain signal on the detector (long camera length), thus incorporating also information concerning the crystallinity of the sample in the micrograph.

The MAS glass-ceramic sample may also serve to compare the images formed with TEM and STEM. In a TEM image in bright-field mode (Figure 6a), the zirconia crystals appear dark in a bright glass matrix. This contrast is caused by both mass thickness effects (i.e. stronger inelastic scattering of primary electrons and absorption of primary electrons by zirconia) and diffraction effects (elastic scattering of primary electrons by the zirconia lattice planes). On the contrary, the STEM-HAADF micrograph in Figure 6b shows bright zirconia crystals in a dark matrix because the signal collected by the annular HAADF detector from the electron beam scattered at large angles is much more intense for the heavy Zr atoms than for the relatively light Mg, Al, Si, and O atoms of the glass.

A big advantage of STEM analysis is of course that one can use the primary electron beam for other purposes than just imaging of the sample. With nanobeam diffraction, one can address areas as small as a few nanometers to generate diffractions patterns from which crystallographic structures can be analyzed in great detail, with a probe diameter lower than 5 nm, that can be moved over the sample to study specific areas with nm resolution. Just as in SEM, it is also possible to detect and analyze secondary signals emerging from the electron beam–specimen interaction, such as X-ray quanta or visible light (CL). Especially EDXS in STEM is an extremely helpful tool for a quick determination of the distribution of

Figure 6 Comparisons of TEM and STEM images of ZrO_2 crystals in the glassy MAS matrix. (a) TEM bright-field and (b) STEM-HAADF micrographs.

chemical elements in a sample at a scale that can be truly nanometric because the sample is so thin that the excitation volume is not subjected to lateral resolution broadening: for a TEM sample thinner than 50–70 nm, the excitation volume is now just the very neck of the interaction volume shown in Figure 1. In modern (S)TEM machines, EDX detectors may cover a large solid angle (>1 steradian) above the sample, thus ensuring fast elemental analysis [23].

With these improvements, most of the problems faced with SEM for the chemical analyses of the MAS glass ceramics are readily overcome. First, there is no need to worry about excitation volume and lateral resolution of the EDX analysis since the sample is *very* thin. Second, the generally higher resolution of TEM systems enables finer details to be seen and analyzed. Third, the increased energy of the primary electron beam (here, a 300 kV acceleration voltage) allows high-energy spectral regions far beyond 10 keV to be accessed so that the $Y\text{-}K_{\alpha}$ (at ≈ 14.9 keV) and $Zr\text{-}K_{\alpha}$ (at ≈ 15.7 keV) lines can now be unambiguously separated.

One might wonder why 300 kV acceleration voltage in TEM does not cause the same charging problems as 30 kV in SEM. The reason is that in a thinner sample the interaction cross sections of a very-high-energy electron beam with matter are getting small enough that a majority of electrons can pass through without any interaction. However, this does not mean that radiation damage is not

at all an issue in TEM. Although the process has a low probability, an electron may directly hit an atom or ion and displace it in what is called a knock-on damage. Besides, one finds that glasses and glass ceramics are prone to damages caused by the electron beam, such as motion or even evaporation of Na, Li, or other volatile elements [24], amorphization, or, conversely, crystallization, to name just a few. The experimental conditions to be used (acceleration voltage, maximum beam dose, etc.) *always* depend on the particular sample investigated and often demand a great deal of expertise and experience. Whereas MAS glasses and glass ceramics are quite robust, lithium aluminosilicate (LAS) materials, in contrast, survive a TEM experiment only if irradiated with electrons of reduced energies (typically ≈ 80 kV) and then might still deteriorate readily if exposed even to moderate electron beam doses [25]. To find suitable conditions, it is thus important that large sample areas be available for testing and that settings can be adjusted and saved in the microscope computer.

An example for the use of STEM-EDXS with high lateral resolution is shown for the MAS glass ceramics in Figure 7. The distributions of selected elements are indicated in false color as evaluated from the intensity of the relevant X-ray K -lines in the pixelwise EDX spectra recorded when the beam was rastered over the sample. Even at comparably low magnification (upper panel of Figure 7), these elemental maps clearly show that spinel

Figure 7 Micrographs of element distribution as determined for the areas shown on the left panels by STEM with a 300 kV acceleration voltage at low (upper panel) and high magnification (lower panel) from the indicated emission lines. The Zr, Al, and Y distributions map the zirconia, spinel, and glass phases, respectively. A dendritic spinel is shown in the lower panels, embedded into a silicon-rich matrix that isolates it from the actual yttrium-rich glass matrix.

Table 1 Composition of the MAS glass (at %),^a where “pristine” denotes the homogeneous, non-annealed sample and “annealed” denotes the residual glass areas in the glass ceramics after annealing.

	Mg	Al	Si	Zr	Y
Nominal	16.5	33.9	41.4	4.2	4.0
EDXS pristine	16.8	33.7	41.1	4.5	3.9
EDXS annealed	11.8	17.2	43.1	2.7	25.2

^a Oxygen not considered because of self-absorption of the low-energy O-K X-rays.

(MgAl₂O₄) is growing on dendritic zirconia as secondary phase (Al can be seen as a “marker” for MgAl₂O₄ here). Furthermore, it is obvious that Y is pushed away from the growing spinels into the residual glassy areas. But other features are also apparent, such as the existence of a silicon-enriched shell between the spinels and the residual glass. At higher magnification (lower panel), additional stunning details are seen, e.g. the dendritic structures formed by the growing spinels when they expand into the surrounding matrix.

In view of the small excitation volume in TEM experiments, it is rather straightforward to compute the relative intensity ratios of the element-specific peaks in an EDX spectra and thus to get a quantitative element distribution of tiny areas within a sample once the system is properly calibrated. In this way, crystallization-induced changes in the composition of the residual glass can, for instance, be investigated, even if the lateral dimensions of the residual glassy areas are a few nm³ only. As shown by Table 1, the STEM-EDX calculated compositions of the pristine green MAS glass are in excellent agreement with the nominal data, whereas important changes are observed after heat treatment for Zr and especially for Y.

3.3 Electron Energy Loss Spectroscopy

In analytical (S)TEM, an additional useful source of information concerns the nature, valence, and coordination of atoms, which affect specifically the energy loss undergone by the primary beam through inelastic scattering by electron clouds within the sample. As in X-ray absorption spectroscopy (XAS) or, more precisely, X-ray near-edge structure spectroscopy (XANES) (see Chapter 2.2), the interaction of a given atom with its local environment, i.e. the influence of the nearest neighbors on its electronic structure, is thus probed with an appropriate spectrometer mounted below the sample, which filters electrons according to their energy loss. This energy loss near-edge structure spectroscopy (ELNES) has certain advantages, such as a superior spatial resolution in comparison with

Figure 8 Al-*L*_{2,3} edge EELS spectra of MAS sample areas that represent either the residual glassy part or the spinel therein.

XANES. In addition, it is applicable to light elements such as Li, Be, or B, whereas appropriate cross sections for X-ray generation typically restricts EDXS to elements heavier than B. On the other hand, quantification of electron energy loss (EEL) spectra is not as straightforward as in EDXS, and one is restricted to energy losses lower than ≈2 keV with EELS. Thus, it complements nicely with EDXS, whose typical spectral domain for useful application starts at approximately 2 keV.

As an example, the excitation of aluminum electrons from the 2p level to empty states above the band-gap energy gives rise to Al-*L*_{2,3} edge EEL spectra where the presence, relative intensity, and energy position of specific features (A–F) bring information on Al coordination (Figure 8). For spinel, the spectrum is, for instance, typical of Al in octahedral coordination [26], which is not observed in the residual glass matrix whose detailed interpretation is actually more complicated because the features in the 100–110 eV energy range are convoluted with the Si-*L* edge signal. Although they are beyond the scope of this chapter, elaborate computation techniques nonetheless exist with which information on coordination can be derived with an increasingly high precision from the intensity and positions of the peaks in EEL spectra [5, 27]. Not all ionization edges are well suited for in-depth analyses, however, the so-called white lines of transition metals being generally favorable cases.

4 Scanning Probe Microscopy

Owing to the inherently nonperiodic arrangement of atoms in glass, use of scanning probes is of special interest for studying the topography of a sample surface and inspecting, for instance, its roughness after polishing.

Besides, information on the structure of a crystal present at the surface can be obtained, especially if some relaxation or reconstruction phenomena have caused a local change of its periodic arrangement.

Among the probe microscopy techniques that have been designed, atomic force microscopy (AFM) is probably the most widespread. Rather than describing its *noncontact* or *tapping* modes, we will restrict ourselves to the basic principle of its *contact* mode, which is sketched in Figure 9. When a cantilever is moved against the sample surface in an x - y raster scan, it is deflected differently depending on the local roughness or composition of the sample surface. Because the deflection can be monitored precisely via the reflection of a laser beam on the cantilever head, it can be kept constant with an appropriate electronic feedback loop (constant-force AFM). If this force is modulated in the z -direction with a certain oscillation frequency, the sample surface resists the oscillation, so the cantilever bends according to the stiffness of the probed sample area. With this force-modulation approach, the information obtained thus goes farther than surface topography since a certain measure of the surface elasticity is also obtained.

Again the MAS sample illustrates the results that can be obtained with AFM in terms of surface topography and hardness (Figure 10). For a polished surface, identification of the dark (glass) and bright (spinel or zirconia) areas apparent in the micrograph has to rely on SEM

or (S)TEM experiments, but the force-modulation micrograph yields information not available by other means on the much greater hardness of the crystalline phases compared with that of the glass matrix.

Figure 9 Working principle of the atomic force microscope in the contact mode.

Figure 10 Topography (left) and hardness (right) contrasts between spinel and the glass matrix of the MAS sample in AFM micrographs.

(a) Unetched, polished sample and (b) superficially etched sample. Hardness contrast derived from a mapping of the cantilever amplitude damping.

Because different phases are not attacked by acid solutions at the same rate, etching of glass-ceramic surfaces by HF or HF–HNO₃ solutions can enhance the microstructure contrast in AFM observations. In the MAS sample, the SiO₂-rich glass is, for instance, more prone to dissolution upon HF etching than spinel and zirconia, so the dendritic- or “finger-like” shape of the spinel growth front is more clearly seen (Figure 10b). In contrast, the large residual glassy areas that are much less etched have a different composition. Indeed, from the EDXS results described in Section 3.2, it is known that these residual glassy areas are strongly enriched in Y.

5 X-Ray Microscopy

As applied to glasses and glass ceramics, the aforementioned techniques give detailed insights into microstructures and even nanostructures. However, some difficulties remain to be faced. Like electron microscopy or scanning probe microscopy, imaging techniques usually require some sort of (often demanding) sample preparation. If preparation artifacts are avoided, one ends up with a wealth of information about morphology, chemistry, and crystallography for a sample volume of only a few 100 nm³. As stated in the Introduction, it is, therefore, highly desirable either to complement such detailed investigation down to the sub-nanometer scale with more integrating techniques or to find ways to assess larger volumes, even at the risk of losing spatial resolution.

In this respect, X-ray microscopy (XRM) has emerged as a new kind of imaging technique that is both nondestructive and capable of offering a three-dimensional (3-D) description of the sample bulk. With a maximum 3-D spatial resolution of 50 nm, it cannot compete with TEM. But sample preparation (for example, with laser micromachining) is rather straightforward, so XRM gives quick answers in the form of a 3-D density mapping of a reasonably large piece of specimen that may represent the sample bulk.

The technique is based on shadow casting of X-rays stemming from a point source and going through the sample volume to end up onto a CCD camera. It is similar to X-ray computed tomography, from which it differs by the fact that the X-rays are focused within the sample, rather than the sample being illuminated as a whole, and that the signal is further magnified optically on the screen. Because this magnification is made from the central part of the sample, image aberrations are minimized, and enhanced X-ray optics (derived from synchrotron beamlines) help to achieve an unprecedented resolution. But as with X-ray computed tomography, the acquisition of series of images for a rotating sample, followed by

Figure 11 Three-dimensional (3-D) representation of X-ray microscopy data from a truncated cone that was laser micromachined from the MAS glass ceramic. (a) Entire dataset with denser volumes in brighter contrast (green in the false color version) and lighter volumes in darker contrast (blue in the false color version). (b) 3-D visualization of just the high-density regions of the sample, taken from a clipped internal volume of (a) to make segmentation easier. Volume fractions: dense inclusions: 23%, lower-density material: 77% (see electronic version for color figures).

image processing of the resulting datasets, can yield 3-D pictures.

For the MAS sample repeatedly considered here, such a 3-D picture clearly shows how the high- and low-density components are interconnected (Figure 11), the former and latter likely being the Y-bearing glass and the spinel, respectively. Owing to a lack of elemental and spatial resolution, however, yttria in the residual glass and the zirconia needles cannot be discerned.

6 Perspectives

This review of microstructural techniques is not comprehensive. In addition to the variety of spectroscopy techniques such as IR, Raman, XPS, or micro-X-ray fluorescence (Chapters 2.2 and 5.1), which also possess certain spatial-resolution capabilities, electron backscatter diffraction, transmission Kikuchi diffraction for texture analyses, or time-of-flight secondary ion mass spectrometry can also be used to investigate the property–structure relationships in glass-based materials down to a sub-nanometer scale. Because an important feature shared by all of these techniques is their ever-improving resolution and analytical precision, one can expect a better understanding of the way in which valuable mechanical, thermal, optical, or electronic properties are achieved in inhomogeneous materials. Conversely, these observations should help to

design and tailor new materials for specific applications. Of particular interest is a better understanding of crystallization processes, whereby the nucleating phases not only differ generally in chemical composition from the starting glass but can be nonstoichiometric and highly disordered. In this respect, more detailed observations thus should serve as a basis for theoretical investigations in the fascinating field of the coordination and valence changes that are taking place during microstructure evolution. And one can even expect that further instrumental advances will make it possible to check material properties online during glass and glass-ceramic fabrication and figure out at once causes for production failure, such as surface devitrification.

Acknowledgments

We thank Dr. M. Krause and M. Menzel (Fraunhofer IMWS) for performing SEM and AFM experiments, respectively; A. Böbenroth and B. Mühs-Portius (Fraunhofer IMWS) for AFM (etching) and TEM sample preparation, respectively; and Drs. S. Kelly and B. Hornberger (Carl Zeiss Microscopy) for providing us with 3-D XRM data. We also thank Dr. A. Gawronski (Friedrich Schiller University Jena) for making of the MAS glass and glass-ceramic samples. Further, financial support by the German Science Foundation (DFG) by means of various grants is gratefully acknowledged.

Short-range Structure and Order in Oxide Glasses

Jonathan F. Stebbins

Department of Geological Sciences, Stanford University, Stanford, CA, USA

1 Introduction

Information about short-range structure is crucial for understanding, predicting, and optimizing the physical and chemical properties of oxide glasses. Glass structures also provide first approximations for the high-temperature molten precursors of these materials, whether in a glass melting tank or a natural magma system, and thus give fundamental information for understanding and predicting liquid properties [1, 2]. Glasses are often simply categorized as “disordered” solids, lacking the long-range order and the accompanying Bragg diffraction peaks of their crystalline counterparts. The nature and extent of this disorder, however, and how these vary with composition, temperature, and pressure, are of key importance. Much is now qualitatively known about such questions, but quantitative understanding is in many cases just beginning.

Because the same short-range bonding interactions are present in crystals, glasses, and liquids, a sensible starting point for discussions of oxide glass structure is often that of known crystalline compounds. However, this approach has limitations and can be downright misleading. An example is shown in Figure 1, which compares the oxygen ion environments of crystalline and glassy CaTiSiO_5 (titanite), a compound with a particularly high entropy of fusion [3]. Some of the same short-range structures are present in both, but the glass (and thus liquid) has not only quantitatively greater ranges in local structural variables but major qualitative differences in the type and variety of atomic-scale environments. Furthermore,

these types of data typically do not reveal the degree of mixing among the various structural groups, which thus leaves the interesting problem of possible medium-range heterogeneities unanswered.

In this chapter, we begin with a brief summary of the short-range structures of well-known single-component network oxide glasses, and compare and contrast the different mechanisms by which addition of network modifiers cause rearrangement of these structures. We then continue with the type and degrees of order/disorder that result from mixing of multiple modifier and/or network cations in multicomponent glasses and liquids. Silicates, aluminosilicates, borates, germanates, and phosphates are emphasized as these are most common in nature and in technology. However, it is important to note that other glasses, based on oxides that also have small, highly charged cations and that thus can behave as “network formers” in some ranges of compositions, can provide intriguing clues as to important principles of glass structure/property relationships. These include (at least) TeO_2 , As_2O_5 , V_2O_5 , Sb_2O_5 , CrO_3 , and MoO_3 .

2 One-component Oxide Glass Formers

Pure SiO_2 , GeO_2 , and B_2O_3 readily form glasses on cooling from the melt, and epitomize the “network-forming” oxides. The Si^{4+} , Ge^{4+} , and B^{3+} cations all have high valences, relatively high electronegativities, and are small enough to be stable in four- and/or three-coordination with oxygen. The strongly bonded and interconnected structure that results contributes to high liquid viscosities, slow diffusion, and crystal growth rates, and thus good glass-forming ability.

Of the three pure-oxide glass formers, silica is by far the best studied because of its many important technological

Figure 1 Oxygen linkages in crystalline and glassy CaTiSiO_5 as seen by ^{17}O MAS (magic-angle-spinning) NMR. Ti–O–Ti and Si–O–Ti oxygens are abundant in both, but peaks are much narrower in the crystal because of the long-range order, whereas the glass contains much greater local-scale disorder. The glass also contains abundant structural groups absent from this crystal, such as Si–O–Si and Si–O–Ca oxygens, requiring a more complex structure. Spinning sidebands are marked by black dots. *Source:* Modified from [3].

applications, although many of its properties are anomalous with respect to multicomponent silicate glasses. The structures of the multiple (low pressure) crystalline forms of silica are all comprised of three-dimensional networks of corner-shared tetrahedra linked by Si–O–Si “bridging oxygens” (BO). Early X-ray scattering results confirmed this coordination in the glass and yielded mean Si–O bond distances similar to those in the crystals (Figure 2) [4], as have many subsequent diffraction and spectroscopic studies. The short-range disorder is most obvious in distributions of Si–O–Si bond angles, which have been determined from methods such as X-ray and neutron scattering, vibrational spectroscopy, and ^{29}Si and ^{17}O NMR. This disorder is in turn related to distributions in the sizes and connections among the rings that can be mapped in structural models. The lack of other major sources of disorder is probably why the entropy difference between the liquid and crystal is the lowest known for any oxide [5].

Ambient-pressure crystalline borates are known to contain both BO_4 tetrahedra and BO_3 triangles, whereas pure B_2O_3 consists only of the latter. Early X-ray scattering

Figure 2 Radial distribution curves derived in an early X-ray scattering study of Na_2O – SiO_2 glasses, with mole fractions of Na_2O labeled. Estimated coordination numbers for Si–O (recognized by the authors to be equivalent to 4.0) and Na–O are shown under the corresponding peaks, and mean interatomic distances are shown above the curves. *Source:* Reprinted with permission from [4].

studies again were fundamental to understanding the glass, which also contains only the three-coordinated species. Subsequent evidence, from diffraction and spectroscopy, confirms this conclusion. A long controversy over how the BO_3 triangles are interconnected has largely been resolved in favor of abundant three-membered “boroxol” rings (Figure 3), thanks to methods such as combinations of neutron and X-ray diffraction with structural modeling and sophisticated two-dimensional (2-D) and multinuclear NMR. These have been applied in more complex compositions as well (Sections 3–5). Pure GeO_2 can take on both tetrahedral and octahedral structures even in ambient-pressure crystals, and compounds such as alkali germanates often contain mixtures of GeO_4 , GeO_6 , and even GeO_5 groups. Diffraction and spectroscopic studies agree that pure GeO_2 glass at ambient pressure is comprised mostly or entirely of tetrahedral groups and is thus a good analog for SiO_2 . In-situ X-ray absorption spectroscopy (XAS) and diffraction experiments on both SiO_2 and GeO_2 glasses at tens of GPa pressures indicate substantial bond lengthening for both Ge–O and Si–O and increases in Ge and Si coordination numbers, these effects taking place at much higher pressures for Si than for Ge.

Figure 3 Two-dimensional sketch of a mixed network oxide glass such as $\text{B}_2\text{O}_3\text{--SiO}_2$. “Boroxol” groups (a typical one is circled) are particularly abundant in pure B_2O_3 glass. Another aspect of the disorder is the degree of mixing of network cations, which can be determined by methods that “count” the number of different oxygen bridges, e.g. between BO_3 groups (light color) and SiO_4 units (darker color).

3 Modifying the Network: Silicates and Phosphates

When an oxide of a larger, lower charged cation (e.g. Na_2O or CaO) is added to liquid silica, the oxide ion (O^{2-}) can interact with network oxygen bridges between SiO_4 tetrahedra to form “non-bridging” oxygens (NBO), as symbolized by a reaction illustrated by Figure 4:

Results from even the earliest X-ray scattering studies of alkali silicate glasses (Figure 2) supported this basic concept [4]. Likewise, many vibrational spectroscopy studies have demonstrated increasing proportions of NBOs within silicate tetrahedra with increasing modifier contents. “Network-modifier” cations such as Na^+ and Ca^{2+} balance the negative charge on each of the NBOs: bond-valence considerations generally require several such cations for each NBO as seen in the corresponding

Figure 4 Two-dimensional representation of the modification of a glass network induced by addition of an alkali oxide M_2O . The SiO_4 , BO_3 , GeO_4 (etc.) polyhedra are symbolized by the triangles. (top) Conversion of one bridging oxygen to two non-bridging oxygens (small, dark circles), which are charge balanced by the alkali cation (large circles). (bottom) Increase in the coordination numbers of two network cations (squares) and the formation of bridging oxygens with partial negative charges (small, light circles). Conversion between these two types of modified network, with either pressure or composition, is indicated by the vertical arrows.

crystals. At low modifier concentrations, there are not enough NBOs to fill the coordination sphere of each modifier, with typically five to eight oxygens needed. This means that without cation clustering to allow nonrandom sharing of NBOs, some BOs must also serve this coordinating role. With higher field strengths of the modifier cations (defined as the formal charge divided by the square of the mean cation–oxygen distance), this arrangement is increasingly unstable and can lead to liquid–liquid phase separation over wider ranges of composition. With very high field-strength modifiers (e.g. La^{3+} , Zr^{4+}), or for cations with relatively high electronegativities (e.g. Sn^{2+} , Pb^{2+}), the structural and chemical distinctions between BO and NBO may begin to blur, in that some “modifier” cations may take on low coordination numbers and $\text{Si} - \text{O} - \text{M}$ linkages may become relatively strong. Such cations are often described as having “intermediate” character.

Reaction (1) can also be considered as a description of chemical equilibrium among oxygen ion species, and has long played a prominent role in models of the thermodynamics of low-silica metallurgical slags. Conventional views have suggested that “unreacted” or “free” oxide ions are probably only abundant in low-silica glasses and/or in systems with highly electronegative modifiers such as Sn^{2+} and Pb^{2+} . Oxygen ion speciation in some silicate glass compositions can be measured with methods such as XPS and ^{17}O NMR, or estimated indirectly through techniques that provide information on silicate anionic

speciation such as Raman spectroscopy and ^{29}Si NMR (see Section 7.2). Some such studies have suggested the presence of a few percent of “free” oxide ions in compositions well outside the range where they are required by stoichiometry alone, e.g. at silica contents >33.3 mol% in the MgO-SiO_2 binary. As containerless melting and quenching methods have made the formation of very low silica glasses possible (even into the “sub-orthosilicate” range, e.g. lower silica than in Mg_2SiO_4), it has become possible to quantify more clearly this most basic aspect of silicate structure [6].

In “modified,” ambient-pressure silicate glasses, only tiny fractions of SiO_5 groups have been detected in a few alkali silicates. However, high pressures, or high P_2O_5 contents, can lead to the formation of substantial fractions of both SiO_5 and SiO_6 , which will contribute to the overall network disorder as well as to density increase. For example, both an unusual high-pressure crystalline phase of CaSi_2O_5 and its glassy equivalent clearly have all three Si coordinations (Figure 5). A number of in-situ, high-pressure studies, particularly by Raman spectroscopy, have suggested that considerable structural relaxation, and reversion to lower network cation coordination, can take place on decompression of a glass, even at ambient temperature. A few of these have probably also taken samples above T_g at high pressure. The small cationic radius and high charge of P^{5+} makes P_2O_5 another well-known network-forming oxide. Over wide

ranges of composition, two-component and more complex phosphate liquids are stable and can be quenched to glasses. These have been extensively studied, particularly by vibrational spectroscopy and ^{31}P MAS NMR. All phosphorus is present in PO_4 tetrahedra. As in silicate glasses, these are linked together to form chains of varying length as well as more complex structures. The roles of BO and modifier oxides in phosphate glasses are analogous to those in silicates, as are the considerations of anionic speciation discussed in Section 7.2.

4 Modifying the Network: Borates and Germanates

Contrary to what is found in ambient-pressure silicates and phosphates, a different type of network modification takes place when oxides of low-valence cations are initially added to B_2O_3 or to GeO_2 , facilitated by the energetically “easy” transitions of network cations between two (BO_3, BO_4) or even three ($\text{GeO}_4, \text{GeO}_5, \text{GeO}_6$) coordination states. Instead of only forming NBOs, the added oxide ion serves primarily to increase the coordination number of the network cation so that the network remains fully connected by BO, if the definition of the latter is expanded to include linkages with the higher-coordinated network cations. (It is important to note, of course, that oxygen bridges between network cations may be energetically quite distinct, and have differing implications for bulk properties, as the network cation coordination varies.) If NBOs do form, their concentrations are much lower than produced in the corresponding silicate equilibria. The “modifier” cations are coordinated primarily by BO, some of which will have partial negative formal charges, e.g. $-1/4$ on the BO linking a BO_3 with a BO_4 group. This mechanism (Figure 4) predominates up to about 20–30 mol% modifier oxide, at which point the formation of “normal” NBOs, as in silicates, begins to become important. At least part of this turnover may result from the difficulty of packing enough low-charge modifier cations around BOs with higher formal charges, i.e. $-1/2$ on the link between two BO_4 groups, and in turn this can be affected by the cation field strength and dilution of the borate network by silica. At higher modifier contents, much or even most of the network cation coordination returns to the lower state, BO_3 or GeO_4 . These compositionally induced transitions in the network cation coordination are generally mirrored in the structures of the binary crystals, and result in strongly nonlinear property–composition relationships in both the melts and glasses, e.g. density and glass transition temperature.

Figure 5 Silicate structural groups in a high-pressure, triclinic crystalline phase of CaSi_2O_5 and in its isochemical glass quenched from the melt at 10 GPa, showing the correspondence of signals for Si with 4, 5, and 6 oxygen neighbors in ^{29}Si MAS NMR spectra. Source: Modified from [7].

This mechanism is most precisely defined in alkali borate glasses, for which ^{11}B NMR has long been applied to measure directly BO_3 and BO_4 contents [8]. Raman spectroscopy can also detect this coordination shift, and can be more readily applied at high temperatures and pressures. The structural transition with composition can be symbolized by the reaction, which incorporates the reaction of O^{2-} with BOs to form NBOs:

This reaction can also be taken as a statement of chemical equilibrium among melt species. Shifts with temperature have been determined from both in-situ, high-temperature vibrational and NMR spectroscopy and studies of glasses prepared at different cooling rates and thus with different fictive temperatures [9]. The lower coordination state (left hand side) is generally favored at higher temperature, meaning that the enthalpy change for the reaction as written is negative. In boron-rich systems, this coordination change can be a major contributor to the overall configurational heat capacity and enthalpy of the liquid; changes in the abundances and mixing of the boron coordinations will clearly affect the configurational entropy as well. At least in borosilicate glasses, modifier cations with higher field strengths tend to favor the formation of NBOs and thus lower boron coordination numbers. Spectroscopy on quenched, decompressed glasses has shown that this mechanism leads to boron coordination increase at high pressure [10]; a few in-situ studies by X-ray and other methods have observed this process more directly.

Analogous structural transitions that take place as modifier oxides are added to GeO_2 . Alkali germanate glasses and melts have density maxima at roughly 15–20% M_2O , the compositions near which crystal structures are made up of mixtures of GeO_4 , GeO_6 , and even GeO_5 groups. Although these groups cannot be individually quantified in glasses as readily as those in boron-containing compositions, XRD and neutron diffraction demonstrate the accompanying changes in mean Ge–O distances. Also, ^{17}O NMR can distinguish BOs, NBOs, and other species in germanates and confirms the transition from a primarily “borate-like” mechanism at low modifier contents (mixed low- and high-coordination of Ge, most or all BO in the broad sense of the term) to a “silicate-like” mechanism (GeO_4 and “normal” NBO formation) at high modifier contents. Germanate crystals, glasses, and melts are often considered as at least rough analogs for silicates at elevated pressures. If the changes in network cation coordination with composition are as complex in silicate melts at high pressures, then highly nonlinear compositional effects on melt properties may be expected.

5 Network Cations in Aluminosilicates

In most readily formed multicomponent oxide glasses, Al^{3+} is a network former predominantly present as AlO_4 tetrahedra. The latter are compositionally equivalent to $\text{AlO}_{4/2}$ if oxygen sharing is taken into account. Because the alumina chemical component (Al_2O_3 or $\text{AlO}_{3/2}$) has insufficient oxygen to form this species, one NBO, if present, will be converted to a BO for each added Al cation. Simple models of aluminosilicate melt structure have long assumed that, when alumina contents become large enough to balance all of modifier oxides (e.g. moles of Al_2O_3 = moles of Na_2O or CaO), NBO contents are reduced to zero and the glass or melt structure is comprised entirely of fully connected tetrahedra, by analogy with framework aluminosilicate crystals such as feldspars (e.g. $\text{NaAlSi}_3\text{O}_8$, $\text{CaAl}_2\text{Si}_2\text{O}_8$). This is a good approximation in some systems, especially those with alkali oxide modifiers only, and is supported by long-known changes in properties with composition as well as diffraction and spectroscopic data. As alumina is added to alkali silicate melts and glasses, for example, the alkali cations are coordinated by fewer NBOs and more BOs, some of which will have partial negative formal charges, e.g. $-1/4$ for Si–O–Al and $-1/2$ for Al–O–Al. This change in role can be described as a transition from “network-modifying” to “charge-compensating” cation.

However, detailed spectroscopic studies, especially by ^{27}Al and ^{17}O NMR and Raman, show that the structure can be more complex than indicated by this model, particularly in systems with modifier cations of high field strength. In Ca and Mg aluminosilicates, for example, significant concentrations of AlO_5 (typically 4–8% of Al cations) and even small amounts of AlO_6 groups are present throughout most of the glass-forming regions [11]. Some NBOs also persist well into the peraluminous compositional range (e.g. with moles of $\text{Al}_2\text{O}_3 > \text{CaO}$). Trivalent modifier cations such as Y^{3+} and La^{3+} promote this shift in Al coordination, which increases even more obviously in peraluminous compositions and in aluminoborates and aluminophosphates. The mixing of these Al coordinations in the network must contribute to configurational entropy and related properties. As noted in Section 3, the distinction between “bridging” and “non-bridging” oxygens becomes blurred as network cations increase in coordination number and their bonds to oxygen lengthen and weaken, complicating simple structure–property hypotheses. A few in-situ X-ray diffraction and Raman studies, and more detailed research on quenched, decompressed glasses, have clearly shown increases in Al coordination with pressure, which occurs more readily than for Si. NMR studies of glasses quenched

from high-pressure melts have shown that Al coordination increase is promoted by modifier cations with higher field strength [10].

6 Short-range Order and Modifier Cations

The relatively large, low-charge cations that can serve as “network modifiers” in oxide glasses comprise much of the periodic table, so that their behavior can only be generally summarized here. Information about their local structural environments has been most commonly obtained from XAS, both XANES and EXAFS [12], from optical spectroscopy for many transition metal and rare earth cations, from Mössbauer for Fe^{2+} and Fe^{3+} , and from modeling of neutron and X-ray diffraction data. In a few cases, notably for ${}^6\text{Li}$, ${}^{23}\text{Na}$, ${}^{25}\text{Mg}$, and ${}^{207}\text{Pb}$, NMR has begun to contribute as well. In a number of oxide glass systems, the possibilities of substitution of isotopes of modifier cations with different neutron scattering cross sections (e.g. ${}^{44}\text{Ca}$ – ${}^{40}\text{Ca}$) has allowed cation-specific pair distribution functions to be derived from differential measurements, which can give unique details of ordering out to several cation shells. All of these types of data usually indicate some disorder in the first shell and, in some cases, mixes of cation coordination. Most commonly, coordination numbers are similar to those of known crystals or somewhat lower, as can be expected from the lower densities of the glass and liquid phases. Fitting of EXAFS data for some modifier cations has provided important clues about cation first neighbors and on whether these mix randomly, which can be important not only for thermodynamic models but for optical and magnetic properties. In systems with strong nuclear dipolar couplings, such as for ${}^{23}\text{Na}$ and ${}^7\text{Li}$ in alkali silicate and borate glasses, detailed studies of NMR line shapes and relaxation can give estimates of mean distances among the modifier cations [13]. With these data one can discriminate between models of random, spatially homogeneous distributions and of nonrandom arrangements with shorter average cation–cation separations. The latter feature is found in models in which modifiers are clustered in regions with relatively high NBO concentrations, for example, those in 2-D “channels” thought to be important in ion transport [1].

The coordination number of a given modifier cation often depends on glass composition. For example, the coordination number of an alkali cation should increase as the fraction of coordinating oxygens that are NBO (vs. BO) decreases with increasing silica or alumina content, and thus the negative charge per oxygen is reduced. This type of change has been measured by ${}^{23}\text{Na}$ NMR and other methods. In cases where glass color is caused by electronic transitions in cations such as transition

Figure 6 Optical spectra for glasses in which Ni^{2+} coordination changes from primarily 4 to 5 to 6 coordinated as alkali content is decreased. The bulk glass color changes from purple to brown to green. Source: Modified from [14].

metals and rare earths, changing site geometry or coordination number with composition can have dramatic visible and spectroscopic consequences (Figure 6). If more than one modifier cation is present in the system, that with the higher field strength can outcompete another with a lower field strength for coordination by NBOs, displacing the latter cations into sites with higher coordination number (and/or to those with more BOs) as composition changes. This type of site ordering is probably part of the explanation for the commonly seen “mixed alkali” effects, where cation diffusion and ionic conductivity can be slowed by orders of magnitude relative to those in single-modifier compositions. At higher temperatures, increased disorder with respect to modifier cations can be a major contributor to configurational entropies and is marked, for example, by the enhancement of the entropy of fusion of diopside ($\text{CaMgSi}_2\text{O}_6$) relative to those of enstatite ($\text{Mg}_2\text{Si}_2\text{O}_6$) and wollastonite ($\text{Ca}_2\text{Si}_2\text{O}_6$) [2].

The charges and sizes of network-modifier cations, as in part captured by their field strength and reflected by their coordination numbers, can have huge effects on the network structure of oxide glasses and on both glass and melt properties. When the coordination of the network cation can readily change, as for boron and aluminum in some systems, higher field-strength modifiers can either decrease (B) or increase (Al) the network cation coordination, again probably through a process of formation of and/or competition for NBOs. These effects are much less well known, but could be expected in germanates and in high-pressure silicates.

7 Interactions of Network Modifiers and Network Order/Disorder

7.1 Order and Disorder of Bridging and Non-bridging Oxygens

In oxide glasses with more than one type of network-forming cation, NBOs and BOs could be equally

distributed on all such cations, or could be ordered in some way. The latter is generally the case. Raman spectra of aluminosilicates have suggested that most NBOs are on Si and that most AlO_4 groups thus have four BO, when composition permits. This result has been directly confirmed by ^{17}O NMR in Ca aluminosilicates. Comparable studies in a few borosilicates have observed B-NBO and the predominant Si-NBO.

For systems with more than one type of modifier cation, large differences in size or charge might be expected to lead to some kind of ordering. This can be sampled by methods that “see” the coordination environments of oxygen species directly. For example, both one- and two-2-D ^{17}O NMR spectra have shown that chemical shift distributions in mixed Na/K and mixed Ca/Mg silicate glasses are consistent with random distributions of the two cations around the NBOs, consistent with deductions from viscosity measurements and estimated configurational entropies. In contrast, the large field-strength difference between K^+ and Mg^{2+} leads to a concentration of the latter around the available NBO sites. This approach has shown the considerable complexity of order/disorder patterns that can occur in the distributions of modifier- and charge-compensator cations around both NBO and BO sites in a number of other mixed-cation silicates and aluminosilicates. Decreases in this type of ordering might be expected from entropic considerations at higher temperatures in the liquids.

7.2 Q^n Speciation

In silicate and phosphate glasses, the best-known aspect of network order/disorder, as affected by the modifier cations, involves the distributions of the NBOs. One can sample these distributions by counting the proportions of “ Q^n ” species, defined as tetrahedral groups with n BOs and $4-n$ NBOs. Such measurements were originally done by Raman spectroscopy [2]. At least in some simple systems such as alkali silicates and phosphates, these proportions can often be readily quantified by ^{29}Si or ^{31}P NMR; such results can be used to evaluate cross sections for vibrational spectroscopy as well. In both approaches, peak fitting and associated assumptions about line shapes are usually required and can lead to some ambiguity. An early and important question was whether the number of Q^n species present in a glass was the minimum derived from stoichiometry (in general two, but only one at special compositions), or whether entropy induced a greater variety. The clear detection of Q^2 , Q^3 , and Q^4 species in glasses such as $\text{Na}_2\text{Si}_2\text{O}_5$, which could contain only Q^3 as in the crystal, confirmed the latter view. Simple equilibria among Q^n species can be defined for $n = 1, 2, 3$:

Apparent equilibrium constants k_n for such reactions have been evaluated from Raman and NMR data on glasses, including 2-D ^{29}Si NMR on Ca and Mg silicates [15]. Higher field-strength modifiers push these reactions to the right (increasing k_n), presumably favoring the concentration of more NBOs around some Si sites and thus better local charge balance for small, highly charged modifiers. More Q^4 species are also generated, which correlates with higher thermodynamic activities of silica as deduced from phase diagrams [5]. In the range of observed speciation, greater k_n values lead to greater contributions to the configurational entropy if models of random mixing of the Q^n species are considered. But enhanced ordering of NBOs around higher field-strength cations could counter this effect to some degree and, in the extreme, could lead to cation clustering and even incipient phase separation. Shifts of such equilibria have been measured with both in-situ high-temperature Raman spectroscopy and NMR on glasses with increasing fictive temperatures, the results from the two methods often agreeing well. Estimated enthalpies of reaction are usually positive, but are less so for higher field-strength cations. If a random model is assumed (which can in some cases be tested by NMR methods yielding spatial correlations of different species), mixing of observed Q^n populations can contribute a substantial fraction of the calorimetrically determined entropy differences between glasses and crystals.

Complementary to these results for glasses in the normal, high-silica, glass-forming range are the recent findings for orthosilicate (e.g. Mg_2SiO_4) and even “sub-orthosilicate” glasses formed by quenching in laser-heated, gas-levitated, containerless melting systems. Here, significant concentrations of Q^1 species can be observed by Raman and ^{29}Si NMR, requiring as well the presence of nonstoichiometric “free oxide” ions. Direct evidence for the latter can be seen in ^{17}O NMR spectra [6].

7.3 Order/Disorder in Network Linkages

The distribution of network cations (e.g. Si^{4+} , Al^{3+} , B^{3+} , P^{5+}) around BO in multicomponent oxide glasses and melts is in principle relatively simple to characterize, as each BO has only two such neighbors. This is a quite important problem, though, as it defines the extent of disorder among the various network components as well as the partitioning of partial charges on the BO, which in turn affects ordering of modifier or charge-compensator cations. Multiple-quantum ^{17}O NMR has allowed such distributions to be directly quantified in some systems, through direct counting of proportions of different linkages among network species.

In crystalline, framework aluminosilicates such as feldspars and zeolites, diffraction and NMR studies have generally shown that Al–O–Al linkages are “avoided”, if

stoichiometry allows, leading to a high degree of ordering when Al/Si = 1, as for example in anorthite ($\text{CaAl}_2\text{Si}_2\text{O}_8$) and nepheline (NaAlSiO_4) in which all the oxygens are present as Si–O–Al linkages. This ordering presumably is related to the energetic and/or geometric unfavorability of bringing enough of the charge-compensating cations close to the relatively highly charged (formally $-1/2$) Al–O–Al linkages. There are notable exceptions for disordered crystals formed by rapid devitrification of glasses (e.g. cordierite $\text{Mg}_2\text{Al}_5\text{Si}_4\text{O}_{18}$ and β -eucryptite LiAlSiO_4), and stable tetrahedral framework compounds containing only Al–O–Al linkages are well known (e.g. CaAl_2O_4).

Triple-quantum ^{17}O NMR spectra of alkali aluminosilicate glasses can fully resolve Si–O–Si, Si–O–Al, and Al–O–Al sites. This has enabled more precise formulations of the thermodynamics of equilibria such as:

In terms of distributions of residual negative charges on oxygens, this reaction is analogous to that for the Al-free system (Eq. 3), as one species on the right has a reduced net negative charge (Si–O–Si or $Q^n + 1$) whereas the other has an enhanced charge concentration (Al–O–Al or $Q^n - 1$). In NaAlSiO_4 glass, the observation of about 10% of Al–O–Al confirmed that aluminum avoidance is not perfect, but also that this aspect of the structure is closer to ordered than to fully disordered, at least near the glass transition temperature. Further studies of other Na, Li, and Ca aluminosilicates, complemented by ^{29}Si NMR spectra, showed that the concentration of negative charge, now in the form of Al–O–Al linkages, is favored by higher field-strength cations (as for the distribution of Q^n species in Al-free silicates) [5]. Thermodynamic modeling of the effects of Al/Si ratio on speciation predicted heats of reactions that are consistent with solution

calorimetry and that were, for a few compositions, confirmed by observed increases in Al/Si disorder in glasses with higher fictive temperatures, making a larger contribution to configurational heat capacity. Subsequent extensive work on high-pressure aluminosilicates has begun to elucidate the much more complex linkages among not only tetrahedral network species but five- and six-coordinated Al and Si, where the mixing of all of these network species presumably contributes to increases in configurational entropy [16].

The same experimental approach can, in some borosilicate glass compositions, quantify the extent of mixing of boron and silicon network cations, which can be much greater than considered in early models based primarily on ^{11}B NMR data (Figure 3). In compositions with modifier oxides, the structure is further complicated by the presence of both BO_3 and BO_4 groups. As for aluminosilicates, relatively highly charged B–O–B linkages between two of the latter seem to be at least partially “avoided.” When pairs of network cations are present that can have strong nuclear dipolar couplings, notably ^{11}B and ^{27}Al , or ^{27}Al and ^{31}P , double-resonance NMR methods can reveal their relative proximities and even the correlations of species with multiple coordination environments, for example of BO_3 groups with AlO_4 [17]. These findings again can provide important constraints on mixing and contributions to order/disorder.

8 Perspectives

Technical advances continue to increase the quality, depth, and breadth of information that can be obtained about short-range structure and order in oxide glasses, for example, microscale XAS, X-ray Raman, improved

Figure 7 Partial pair distribution functions $g_{ij}(r)$ calculated from a “reverse Monte Carlo” model combining X-ray and neutron diffraction data for various CaSiO_3 – MgSiO_3 glasses. Source: Reprinted with permission from [18].

neutron scattering facilities, and NMR at higher magnetic fields and with methods that allow better measurements of internuclear distances and connectivities. Combination of experimental data from different methods, to yield consistent models, is especially powerful, as illustrated in Figure 7 [18]. Some of these approaches are now feasible for in-situ studies of high-temperature liquids and even of liquids at high pressure and temperature. Advances in theory are beginning to allow accurate forward calculation of spectra (e.g. vibrational and NMR) from structural models [19]. This information can then be combined with experimental data to obtain much more complete views of structure, quantitative extent of disorder, and their links to thermodynamic properties that depend critically on configurational entropy, such as viscosity, heat capacity, and the bulk free energy. As researchers move beyond model-dependent fitting and interpretation of spectra of glasses to more complete theoretical analyses, our understanding of the true complexities of these fascinating and useful materials will expand enormously.

The Extended Structure of Glass

George Neville Greaves

Department of Metallurgy and Materials Science, University of Cambridge, Cambridge, UK

1 Introduction

The structure of glass stretches from atomic dimensions and local short-range order (SRO), which is often similar to that of the crystalline state, through intermediate-range order (IRO) and long-range order (LRO) on the nano-scale, which has no parallel in periodic materials. Sometimes IRO and LRO are grouped together as medium-range order (MRO). Glasses have a monolithic structure, which in principle can extend indefinitely from the atomic scale, via the mesoscale to macroscopic dimensions. The extended structure of glass even encompasses the thousands of square meters emerging from the float process, the quenched field of volcanic obsidian, the kilometers of optical fiber, or the reels of metallic glass tape. Contrary to received wisdom, glasses are in general practically defect-free relative to crystalline materials. The fraction of broken bonds in fiber-quality silica, for instance, is a few parts per million. In generating the macroscale, the self-similar configurations of SRO extend virtually continuously everywhere.

The extended structures of glasses generally define their functionality. In silicate and aluminosilicate glasses, for example, tetrahedral bonding through corner-sharing oxygens ensures that the gap between the occupied oxygen p states and unoccupied antibonding sp^3 levels is retained everywhere (this is the so-called HOMO–LUMO gap between the highest occupied and lowest unoccupied molecular orbitals). The existence of relatively few mid-gap defect states in turn guarantees visible and UV transparency for windows, optical components, laser glasses, etc. In metallic glasses, the cohesive potential between the delocalized electron gas and the ion cores

is maintained isotropically throughout the bulk. These features underwrite electrical conductivity and, without the dislocations of crystalline metals, extremely high levels of mechanical hardness and toughness. Likewise, the spin–spin exchange interaction is retained in aperiodic metallic structures, supporting the ferromagnetism exploited in low-loss magnetic metallic glass-transformer cores. Additionally, because most glass formers – either metallic or not – derive from reasonably strong liquids, they have a wide supercooled liquid range and exhibit superplasticity at the softening point (10^8 Pa·s) but virtual rigidity at the glass transition (10^{12} Pa·s). Through Newtonian viscous flow, their monolithic structures enable the easy fabrication of components with essentially any shape, from the industrial dimensions of windscreens down to those of MEMS and nanotechnology.

By contrast, in crystalline materials even the largest industrial single crystals are extremely small by comparison to glass sheet. Large-area crystalline films comprise micron-sized powders such that the facets of polycrystals generate a microstructure of interlacing grain boundaries where functionality generally resides. For example, the ductility of metals, the hardness of ceramics, the strength of steels, and the mesoscale magnetism of metal films mainly derive from the properties of grain boundaries that are often structurally disordered and anisotropic. By comparison glasses are structurally isotropic, and the cracks that affect their mechanical strength are usually restricted to the surface where the atomic structure terminates. The extended structure of glass links the SRO of atoms, molecules, and metallic clusters and geometrically underpins its intrinsic isotropic properties – optical, electronic, dielectric, electrolytic, magnetic, mechanical, etc. This can be visualized through computer-simulated structures (Figure 1), where the open network of a silicate glass is contrasted with the dense close-packed arrangement of a metallic glass.

The respective atomic volumes are 7 and 11 Å³ and are typical of these very different families of glass, but where each share an extended defect-free structure. Reviews of network glasses and metallic glasses can be found in [1, 3], respectively.

In this chapter we consider how several experimental techniques are required to access the extended structure of glass (Section 2), from diffraction and inelastic spectroscopies that reveal relationships between SRO, IRO, and LRO structure and dynamics, to microscopy that probes the average projected structure in real space. We then turn to the different types of structural order that characterize network and metallic glasses (Section 3): starting with the SRO, progressing through the configurations of adjacent local structural units that define IRO, and extending through MRO to LRO, the topology of larger agglomerations – clusters, rings, channels, and chains. Beyond these dimensions are those of density fluctuations (DFs) (Section 4), frozen into glasses from the liquid state, which reflect the degree of non-ergodicity frozen in at the glass transition. In particular, DFs are the agents at super-cooled temperatures that promote phase separation, either in density or in composition. Models of extended glass structure (Section 5) are next described and include conceptual models, devised before the advent of computational methods but still useful heuristically, and large computerized models that have been developed since.

Using this approach, we show how structural heterogeneity in glasses (Section 6) can be modeled in terms of minority-component channels percolating through the majority network or metallic structure. Here, as elsewhere, the extended structure of glass is linked with its applications. Finally, we outline perspectives for future work (Section 7).

Acronyms

AFM	atomic force microscopy
BO	bridging oxygens
BP	boson peak
CN	coordination number
CRN	continuous random network
DAS	dynamic-angle spinning nuclear magnetic resonance
NMR	density fluctuations
DF	density functional theory
DFT	density fluctuations
DRPHS	dense random packing of hard spheres
EXAFS	extended X-ray absorption fine structure
HR TEM	high-resolution transmission electron microscopy
INS	inelastic neutron scattering
IXS	inelastic X-ray scattering
IRO	intermediate-range order

LRO	long-range order
MAS	magic angle spinning nuclear magnetic
NMR	resonance
MD	molecular dynamics
MRO	medium-range order
MRN	modified random network
NBED	nanobeam electron diffraction
NBO	nonbridging oxygens
PSG	phase-separated glasses
RMC	reverse Monte Carlo
SRO	short-range order
VDOS	vibrational density of states

2 Extended Structure of Glass: The Need for a Multiplicity of Techniques

In addressing the extended structure of glasses, a wide portfolio of techniques has developed [1, 3, 5]. For many years the principal experimental method has been X-ray and neutron scattering [6], initially concentrating on the radial distribution function (RDF) from which the radially averaged local structure $T(r)$ can be determined, as illustrated in Figure 2 for silica glass and the metallic glass $\text{Ca}_{60}\text{Mg}_{25}\text{Cu}_{15}$. The maxima identify interatomic correlations, first between nearest neighbors (SRO) defining the polyhedral or icosahedral building units and then between adjacent units (MRO or IRO), as spelt out in the cartoons. The SRO and IRO in glasses are often similar to their crystalline cousins. On the other hand, topology influences LRO – ring statistics for network glasses [1] and icosahedral packing for metallic glasses ([3], Chapter 7.10) – where mismatching frustrates crystallization.

Attention has subsequently shifted to the measured scattered intensity $i(Q)$ from which the static structure factor $S(Q)$ is obtained, which leads to $T(r)$ via Fourier transform [1]. The scattering vector Q is defined by $Q = 4\pi\sin\theta/\lambda$, where θ is the scattering angle and λ the wavelength of the scattering particles. The $i(Q)$ for the two exemplar glasses are plotted in Figure 3. Two important features are located early on for $Q < 5 \text{ \AA}^{-1}$: the first sharp diffraction peak (FSDP), for which the spacing $2\pi/Q_{\text{FSDP}}$ is a metric for IRO, and the principal peak (PP), which is directly related to the average nearest-neighbor distance $2\pi/Q_{\text{PP}}$ [6, 7]. Both the FSDP and the PP are features common to network glasses as well as metallic glasses (Figure 3). With high-intensity spallation neutron sources, the Q -range reliably reaches $50 \text{ \AA}^{-1}$, enabling the $T(r)$ to be confidently measured to $20 \text{ \AA}$, embracing SRO with LRO.

Figure 2 Contrast between the radially averaged local structure $T(r)$ of directionally and metallically bonded structures as exemplified by the network glass SiO_2 (a) and the bulk metallic glass $\text{Ca}_{60}\text{Mg}_{25}\text{Cu}_{15}$ (b). The short (SRO), intermediate (IRO), long (LRO), and medium (MRO) range orders are identified alongside 2-D schematics of local atomic arrangements. Note the difference in the widths of atomic shells reflecting the bonding strength of covalent networks compared to the dense metallic random packings. Source: Courtesy of A. Hannon (<http://alexhannon.co.uk/DBindex.htm>).

Compared with diffraction techniques used for crystalline materials, diffuse scattering methods seriously underestimate the extended structure of glass, even for monatomic systems. Other independent structural measurements are needed in order to increase the credibility of atomistic models. Although X-ray and neutron $S(Q)$'s are independent measures of the same radially averaged structure, until recently X-ray measurements lacked the extensive Q -range of neutron instruments. However, with the arrival of high-energy X-ray scattering [8], both methods are now compatible and are generally applied sequentially to the same material.

Most glasses, though, are multicomponent, which adds chemical complexity to the radial averaging of

Figure 3 Contrast between the network structure of SiO_2 (a) and the metallic structure of $\text{Ca}_{60}\text{Mg}_{25}\text{Cu}_{15}$ (b) manifest in the scattered intensities $i(Q)$, from which the $T(r)$'s of Figure 2 were obtained. The SRO as defined by the principal peak (PP) and IRO defined by the first sharp diffraction peak (FSDP) are labeled alongside LRO and MRO for each glass. Source: Data courtesy of A. Hannon (<http://alexhannon.co.uk/DBindex.htm>).

three-dimensional (3-D) arrays. More chemically selective techniques are thus generally required, even though isotopic neutron scattering can assist when different isotopes of an element are available [6]. Accordingly, neutron and X-ray scattering are now increasingly complemented by spectroscopies, like magic- and dynamic-angle spinning nuclear magnetic resonance (MAS NMR and DAS NMR), and extended X-ray absorption fine structure (EXAFS) [1, 5, 9]. As these are element specific and increase the mix of independent measurements of the same structure, they add rigor to models of extended glass structure derived from computational methods such as reverse Monte Carlo (RMC) and molecular dynamics

(MD) [1, 10–12]. Moreover, expressed as $S(Q)$, the credibility of predictions of atomic arrangements in glasses can be judged against experimental data quality.

Compared to the direct analysis of experimental RDFs, which dates back to the 1930s, these new combinations of experiment and computational modeling now offer impressive insight into the nature of the extended structure glasses, on the scale of 30 $\text{\AA}$ or more (Figure 1). Often glasses with equivalent local structure lead to images that at first glance appear to be quite dissimilar (Figure 4). The tetrahedral glass network of silica may thus be contrasted with that of amorphous ZIF-8 – one of a newly discovered family of hybrid glasses derived from organic–inorganic materials [14, 15]. The extended structure of silica is perpetuated through corner-sharing SiO_4 tetrahedra (SRO) via bridging oxygens (BOs), IRO ultimately extending to LRO comprising rings of different size (Figure 4). The geometry of amorphous ZIF-8 [$\text{Zn}(\text{C}_4\text{H}_5\text{N}_2)_2$] develops in a similar way, with Zn atoms tetrahedrally coordinated to 2-methylimidazolate bridges that form into silica-like rings, despite the atomic volume being hugely different, viz. the $11.1 \text{ \AA}^3$ of SiO_2 compared with the $73.4 \text{ \AA}^3$ of amorphous $\text{Zn}(\text{C}_4\text{H}_5\text{N}_2)_2$.

In adding further confidence to modeling extended glass structure, studies of dynamic properties, using inelastic spectroscopies like inelastic neutron scattering (INS) and Raman spectroscopy, have played an important part [1, 5, 16] – principally in highlighting stretching and bending optic mode vibrations between the atom pairs in network glasses and providing fingerprints of the polyhedra and small molecular groups that constitute SRO and aspects of IRO.

At lower frequencies, inelastic spectroscopies like INS access acoustic modes that are generically subsumed into the boson peak, ubiquitous in the glassy state [1, 5, 17–19]. Derived from the localized collective vibrations of groups of atoms, the boson peak relates to the dynamics of MRO and LRO considered to be the source of fast β relaxation [1, 7]. Located at the bottom of the vibrational density of states (VDOS) in the THz region (1 THz = 4.1 meV), the boson peak is generally accepted as comprising quasi-localized transverse vibrational modes (Chapter 3.4 [16, 18]). These vibrations also enhance the specific heat C_p at low temperatures above the Debye threshold – typically around 10 K. Using either INS or excess C_p reveals that the boson peak intensity is directly related to glass density (Figure 5a–d [18, 19]). For zeolites, which share compositions with silicate and aluminosilicates but have characteristically low densities, the different cage-like units that define their nanoporous structures resonate at different THz frequencies [16]. As the temperature or pressure is increased, these subunits collapse [1] through a process of decelerated melting [21], and a glass, similar in density to a melt-quenched glass, is formed

Figure 4 Visualization of MD simulations of two tetrahedral glasses with vastly different atomic volumes but both conforming to the CRN prescription [13]. (a) SiO_2 glass ($11.1 \text{ \AA}^3$). (b) Hybrid glass ZIF-8 ($\text{Zn}(\text{C}_4\text{H}_5\text{N}_2)_2$) ($73.4 \text{ \AA}^3$). Source: Images courtesy of J. Du (a) and W. Chen (b).

with a single boson peak (Figure 5e). In particular, atomic volume and peak intensity I_{BP} are correlated, with the peak frequency ν_{BP} shifting to higher values as the atomic volume falls.

As for metallic glasses (Chapter 7.10), these also exhibit soft collective vibrations whose origins are similar to oxide glasses boson peaks [3, 20]. If these are accessed from low-temperature C_p experiments, then the enthalpy captured at supercooled temperatures can also be recorded. A direct link exists between I_{BP} and the glass

enthalpy, which can be reduced by annealing Figure 5f [20]. As annealing increases, the glass density, ν_{BP} , also increases while I_{BP} decreases (compare Figure 5e and f).

Whereas inelastic scattering $S(\omega)$ measures the VDOS integrated over Q , and the structure factor $S(Q)$ time-averaged atomic distributions, both derive from the dynamic structure factor $S(Q, \omega)$, which through comparisons with experiment affords a global view of the structure and dynamics of glassy systems and melts over extended regions of space and time. Related to $S(Q, \omega)$ is the intermediate scattering function $F(Q, t)$, which registers structural relaxation from liquid to glass as a function of time [1]. In the limit $t \rightarrow \infty$ $F(Q, t)/S(Q)$ yields the non-ergodicity factor $f(Q, T)$, which is particularly relevant in the present context as it records the degree to which a liquid departs from thermodynamic equilibrium as it is supercooled (Section 4.1). It is readily measured using inelastic X-ray scattering (IXS). Structural relaxation is dominated by fast β processes at high temperatures, with slow α processes emerging through the supercooled region, only to be frozen out at the glass transition T_g .

Microscopy has always played a part in glass structure determination, albeit as a distant companion to diffraction and spectroscopy techniques. It originally provided qualitative evidence for IRO [7]. But the SRO and LRO of network glasses can now be imaged [1, 22] with the emergence of atomic-scale resolution by atomic force microscopy (AFM) and high-resolution transmission electron microscopy (HRTEM). With nanobeam electron diffraction (NBED), images can also be obtained for the variety of icosahedral clusters present in metallic glasses [23] (Figure 6).

3 Structural Order over Different Length Scales

3.1 Network Glasses

Network-oxide glass formers like SiO_2 , GeO_2 , P_2O_5 , and B_2O_3 [1] are defined by three- or fourfold directionally bonded polyhedra comprising hybridized units measuring $\sim 2.5 \text{ \AA}$, similar to nearest-neighbor arrangements in crystalline polymorphs [1]. For low-density hybrid glasses like a-ZIF-4 and a-ZIF-8, tetrahedral units are much larger, measuring about $9.5 \text{ \AA}$ [14]. Generally, SRO polyhedra are comparatively rigid, with variations in bond angle of less than 10%. The IRO is located between 3 and $4 \text{ \AA}$ for oxides increasing to $13 \text{ \AA}$ for hybrid glasses, covering correlation distances between SRO polyhedra (Figure 2 [1, 7, 14]). In oxide glasses the interpolyhedral distance is defined by the BO that is also hybridized, with interpolyhedral angles ranging from around 145° for SiO_2 , 130° for

Figure 5 The collective atomic vibrations involved in the boson peak observed either dynamically in the reduced density of states $g(E)/E^2$ (a, b) or thermodynamically in the non-Debye excess low-temperature specific heat C_p/T^3 (c, d) for silica (left) and densified silica (right). Similar features occur in crystalline SiO_2 isomorphs of similar density [18]. (e) INS spectra of the collapse of zeolite Y [16], the cage subunits merging into a single peak of lower intensity I_{BP} as a glass is formed while ν_{BP} increases – dashed arrow. (f) Boson peak in the metallic glass $\text{Zr}_{50}\text{Cu}_{40}\text{Al}_{10}$ [20] where annealing increases the density, but decreases the trapped enthalpy and the C_p/T^3 intensity I_{BP} falls as ν_{BP} increases – dashed arrow. GeO_2 , and P_2O_5 to 120° for B_2O_3 (Figures 1 and 4 [1]). The imidazolate bridge between metal nodes in a-ZIFs is $\sim 145^\circ$ [14]. On average, the rigidity of tetrahedral and bridging angles is similar.

In network glasses LRO begins at around $6 \text{ \AA}$ – the width of a typical sixfold ring (Figures 1 and 4) – and continues as far as out as features in the RDF can be discerned (Figure 2). Providing a direct link with a multiplicity of rings of corner-sharing polyhedra with different sizes, LRO is perpetuated through modest variations in bond angles, as illustrated in Figure 6 with the two-dimensional (2-D) distributions directly observed for silica [1, 22]. Combinations of experimental RDFs with computer simulations afford 3-D models of network topology where rings are often puckered in conformations foreign to crystalline geometries through variation and twisting of dihedral angles (Figures 1 and 4). The network statistics in SiO_2 glass include five-, six-, and sevenfold rings, as illustrated schematically in Figure 7, in contrast to the

sixfold ring topology of crystalline silicates. In addition, three- and fourfold rings are also found, but in much smaller proportions [1, 6]. They have been identified with the oxygen “defects” that give rise to breathing modes in Raman spectra [1]. These miniature rings increase in number when pressure is applied, for example, in indentation experiments. The converse applies in B_2O_3 glass where the network is less 3-D than in SiO_2 and where Raman spectra are instead dominated by the threefold boroxol ring feature [1]. Pressure causes boroxol rings to break up into buckled ribbons, the dimensionality decreasing further.

Another consequence of LRO in network glasses is the quasiperiodic alignment of groups of caged voids associated with the aperiodic network of rings (Figure 7) to which the FSDP at Q_{FSDP} (Figure 2) is attributed [7]. In glass formers like SiO_2 and B_2O_3 , $2\pi/Q_{\text{FSDP}}$ distances lie around $4 \text{ \AA}$. In chalcogenide glasses, such as As_2S_3 and GeSe_2 , SRO polyhedra are larger ($\sim 4 \text{ \AA}$), leading to

Figure 6 Direct observation of the atomic structures of glasses. (a) Atomic force microscopy image from freshly fractured silica in ultra-high vacuum, revealing a 2-D projection of the near-surface structure and showing SRO and fragments of rings – solid and dotted lines – contributing to LRO [24]. (b) Atomic resolution transmission electron microscope image of a graphene-supported silica bilayer, showing SRO and extensive LRO network with a variety of ring structures [22], consistent with Zachariasen’s CRN [13] (Figure 7a). (c) Nanobeam electron diffraction patterns of $Zr_{0.667}Ni_{0.333}$ metallic glass [23] (left), with their simulated patterns (right) in terms of the icosohedra shown in (d). The different SRO reflect the variety of icosohedra in Bernal’s DRPHS model of liquid metals [25] (Figure 7b). *Source:* (a) Reproduced from [24] © (2004) Elsevier; (b) reproduced from [22] © (2012) ACS; (c, d) reproduced from [23] © Nature Publications.

larger quasiperiodic void separations (~ 6 Å). In all cases FSDP distances decrease as pressure is applied but also become more dispersed, the FSDP peak widening and decreasing in intensity with increasing glass density [7].

Importantly these changes in the FSDP properties of network glasses with pressure correlate with those of the boson peak [17], where ν_{BP} increases and I_{BP} decreases with increasing pressure and therefore density, supporting the view that the BP comprises collective atomic motion of large groups of atoms whose breathing frequency increases as their size shrinks. Furthermore, excess C_p in glasses is attributed to a double-well vibrational potential, which, in silica, can be modeled through the librational twisting of pairs of tetrahedral units, underscoring how the dynamics of IRO promote buckling of rings across LRO in network structures.

3.2 Metallic Glasses

In metallic glasses (Chapter 7.10) bonding is directionless and SRO comprises clusters of atoms around 3 Å in

diameter [11, 12]. Coordination numbers (CN) are between 10 and 11 – much greater than in directionally bonded glasses. With respect to crystalline metals, the CNs of metallic glasses exceed 8, the value for bcc structure (8), but fall short of 10, the CNs for fcc and hcp structures. Atomic cluster units in metallic glasses are around 5 Å apart, similar to interpolyhedral IRO distances in network glasses. The interatomic correlations between neighboring cluster units are identifiable out to around 15 Å (Figure 2), similar to the establishment of LRO in network glasses. In these densely packed metallic structures, however, the geometry of bond angles and dihedral angles and ring topology is absent. The sequence from IRO to LRO is usually collectively described as MRO [4], but is less well understood than in network glasses.

Furthermore, compared to supercooled network systems, where high shear viscosity and low atomic diffusion stem from the existence of open structures, the glass-forming ability of densely packed metallic melts is imprecisely understood. In searching for melt compositions that are suitably viscous for conventional glass

Figure 7 Simple two-dimensional models of glass structure created from sparse (a) and dense (b) packing of spheres. (a) The continuous random network (CRN) model of Zachariasen [13] representing a network glass comprising threefold coordinated cations and bridging anions. Different ring sizes (3, 4, 5, 6, 7, 8) perpetuating extended range order are shown. (b) The dense random packing of atomic spheres (DRPHS) model of Bernal [25] showing variations in icosahedral packing, viz. 5, 6, and 7, that promote homogeneous noncrystalline extended range order.

quenching, those associated with deep eutectics can be a guide, but not exclusively so [4, 23]. An overriding requirement, though, resides in achieving the highest atomic packing density in the supercooled state, which is often achieved by “dissolving” smaller atoms. The atomic size ratio for solute to solvent atoms, which yields the most efficient packing, is frequently found to be approximately 0.9 [4].

For complicated high-density geometries, different packing arrangements in metallic glasses are now modeled with computer simulations – mainly RMC, but also *ab initio* MD – the aim being to analyze the variety and

number of different Voronoi polyhedra present [23]. For an atomic size ratio of 0.9, SRO is predominantly icosahedral, the geometry for tessellated quasicrystal structures. In glasses with pronounced chemical order and atomic size ratio lower than 0.9, pentagonal bipyramids replace icosahedra as the dominant Voronoi polyhedra. Because they embody fivefold symmetry, icosahedrons and pentagonal bipyramids frustrate crystalline close packing and represent the geometric counterparts to odd-membered rings in directionally bonded glasses with open structures.

Metallic glasses, like network glasses, are less dense than their crystalline counterparts, the additional free volume being a throwback from the configurational diversity of the supercooled liquid. In contrast to that of network glasses, though, the FSDP in metallic glasses (Figure 3) is considered to derive from scattering from voids interspersed within the SRO of atomic clusters (Figure 7). In Ca–Mg–Cu glasses, Q_{FSDP} is, for example, about $1.2 \text{ \AA}^{-1}$, and the FSDP correlation length about $5 \text{ \AA}$ (Figure 3). In multicomponent alloys Q_{FSDP} is affected by the size distribution of the different metals and its intensity by density. In Ni–Zr–Al, Q_{FSDP} is, for example, about $0.9 \text{ \AA}^{-1}$ with a FSDP correlation length of about $7 \text{ \AA}$.

Also found in metallic glasses, the excess THz modes at the onset of the VDOS and linear low-temperature specific heat first observed in oxide glasses at THz frequencies [7] appear to have a common origin in the behavior of collective transverse acoustic modes at the Ioffe–Regel limit, where the phonon mean free path equates with its wavelength [19]. At this point vibrations no longer propagate, which suggests that LRO vibrations are localized. Demonstrated by computer simulation of Lennard-Jones glass models, collective vibrations in these close-packed structures replicate the scaling down of I_{BP} with density referred to earlier and the increase in ν_{BP} .

4 Structural Aspects of Density Fluctuations

4.1 Non-ergodicity and Elastic Moduli

Beyond the length scales of LRO and MRO are the DFs characteristic of the liquid state. They originate from the dynamics of the liquid state in thermodynamic response to temperature and pressure. Whereas liquids are in equilibrium and ergodic above the melting point, supercooled liquids are non-ergodic at T_g , which is reflected in the size of the non-ergodicity factor $f(Q, T)$ (Section 2). In particular $f(Q \rightarrow 0, T)$ is related to the magnitude of DFs, and as $T \rightarrow T_g$, a dynamic crossover occurs to non-ergodicity – typically $\sim 1.2T_g$. On vitrification DFs increase in amplitude and eventually become frozen in.

In glasses the spatial extent and amplitude of DFs can be determined from IXS and $S(0)$ [1]. In glass formers DFs are typically ≥ 20 Å in scale, their amplitude being proportional to the melt compressibility κ , which is greater for network glasses than metallic glasses, for example, reflecting the considerable differences in atomic packing (Figure 7). In network glasses like silica, light scattering from DFs limits losses in fiber-optic applications [7]. Interestingly the amplitude of DFs is inversely related to Poisson's ratio, which is smaller for oxide glasses, which are usually brittle, than for many metallic glasses, which are tough [17].

4.2 Polyamorphism and Phase Separation

At high degrees of supercooling, liquid–liquid phase transitions have been observed, a phenomenon now commonly referred to as polyamorphism ([26], Chapter 3.9). These phase transitions have been observed in water, supercooled oxides, semiconductors, and metallic alloys, leading to new types of glass, such as low- and high-density amorphous phases – LDA and HDA respectively – each differing in density and entropy but sharing the same composition [1, 14, 21, 26].

In some multicomponent supercooled oxide liquids, on the other hand, atomic diffusion can result in the coexistence of liquids with *different* compositions, the analogue of multiple phases in crystalline systems. On cooling these lead to phase-separated glasses (PSG) – the best-known being borosilicates [7]. Pyrex, for example, combines low thermal expansion with high mechanical strength, whereas Vycor glass owes its special open microporous structure to the continuous silicate phase that is left when the borate phase has been leached out.

In summary, the extended structure of glass connects all of the various ordered regions present on different length scales and underpins the diverse global properties of the glassy state.

5 Models of Glass Structure

5.1 Conceptual Models

Two conceptual models have proved very influential over the years in picturing the overarching aperiodic structure of glass. Zachariasen's continuous random network (CRN), devised for oxide glasses, dates from 1932 [13]. In 1960 Bernal introduced the dense random packing of hard spheres (DRPHS) to describe the structure of liquid metals [25], which has been applied widely to glassy metals once these had been discovered. Both constructs of glass structure, for insulators and metals, respectively, came in advance of experimental techniques that have

since illuminated their strengths as well as their shortcomings. The two models are illustrated in Figure 7, reduced to 2-D arrangements. Presented in this way, they reveal a common basis for constructing aperiodic arrays from contiguous spheres. They markedly differ, however, because each sphere touches just three neighbors in the CRN, resulting in a more open network structure than with the DRPHS where the number of neighboring spheres lies between five and seven. Taken together, though, both the CRN and DRPHS noncrystalline schemes yield a lower density than for their crystalline counterparts, and voids are seen to align mimicking the quasiperiodicity attributed to the FSDP (dashed curves in Figure 7). The increased free volume derives from variations in packing. As such, both CRN and DRPHS offer respective snapshots of the glassy state without informing on the quenching process during which the configurational entropy is generated. With the CRN each sphere embodies the SRO surrounding individual atoms: MO_3 units, for example, mimic SiO_4 tetrahedra in silica glass or BO_3 and BO_4 polyhedra in borate glasses (Figure 7).

The SRO units are interconnected to create corner-sharing networks of directionally bonded atoms perpetuating indefinitely, which in addition provides a conceptual representation of the extended structures of network glass formers. Although amorphous semiconductors were not yet discovered in 1932, the CRN is equally applicable to chalcogenide glasses like As_2S_3 and also to elemental semiconductors like amorphous As and Ge [7]. In all cases fixed CNs and bond lengths are prescribed by the tenets of the CRN. Usually these parameters are informed from crystalline structures even though space group symmetry is broken by variations in bond angles. Distortions between SRO units lead to rings of atoms of different sizes (Figure 7), including odd-membered rings seldom found in the crystalline state. Because of the bond angle flexibility of the CRN, point defects, like vacancies and interstitials, can formally be avoided, which is consistent with the observation that optical-quality glass is almost free of point defects.

By contrast Bernal's DRPHS structure is the geometric outcome of the random packing of spheres, originally ball bearings in a can [25], each representing a metal atom (Figure 7). Designed to model elemental liquid metals, the DRPHS became an approximate structure for glassy metallic alloys where components have similar atomic radii, such as $\text{Pd}_{80}\text{Si}_{20}$. Nearest-neighbor distances in densely packed structures scale with metallic radii, but the packing scheme in three dimensions incorporates icosahedral units avoiding dense-packed crystalline arrangements. By analogy with the CRN, Bernal's model is free from dislocations that render crystalline metals prone to mechanical damage, which qualitatively explains the

exceptional toughness of metallic glasses. Moreover, as the main contribution to metallic electrical resistivity at ambient temperature is governed by the scattering of electrons by irregularities in the positions of core ions, the DRPHS supports the greater electrical resistivity of glassy metals compared to than crystalline metals, enabling the low-loss of *metglas* magnetic transformer cores.

The major success of the Zachariasen and Bernal models has been in reconciling SRO with the extended structure of the glassy state. These model structures are isotropic and homogeneous by definition, however, and as such they fail to account for DFs observed almost universally in network as well as in metallic glasses. The solution to this drawback can only be solved through the computer modeling of large 3-D melt-quenched structures.

5.2 Computational Modeling of Extended Structure

Atomistic modeling of liquids and solids goes back over 50 years. Over the interim period three main approaches have been developed in relation to glass-forming materials (Chapters 2.7 and 2.8): (i) MD, where empirical potentials describing the repulsive and attractive interactions between atoms are used in conjunction with classical dynamics to explore P–T phase space; (ii) RMC, in which sequential adjustments in atomic positions are made to improve agreement with the experimental structure factor $S(Q)$; and (iii) density functional theory (DFT) based on all-electron quantum mechanical methods that replace the empirical potential in MD. At the present time ensembles 300 Å in size are feasible with MD and RMC, whereas *ab initio* DFT MD, which is computationally more demanding, is currently limited to systems of about 15 Å. Empirical 2- and 3-body potentials are formally ionic but have been successful for predicting the structure and dynamics of liquids and glasses where chemical bonding is predominantly directional in character such as in feldspar compositions ([27], Figure 8). Interestingly, RMC and latterly DFT have been used for metallically bonded systems as well ([4] Figure 1).

Neutron $S(Q)$ data from single experiments were originally used with RMC, together with simple constraints, such as nearest interatomic approach, CN, etc., to avoid unphysical SRO [10]. Now other sources of data are used in conjunction, the most common being high-energy X-ray diffraction [8], but these have been augmented by other sources of data – notably EXAFS and MAS NMR spectra [10]. From large models, LRO effects such as clustering, channels, and other sources of heterogeneity can be examined.

In simulating glass structure with MD and DFT, crystalline ensembles are typically “melted” at, say, 5000 K over 10’s of ps until thermodynamic equilibrium is reached, after which they are cooled at ~1 K/ps, through the supercooled regime and glass transition, to a glass at ambient temperature. At each stage the SRO of bond lengths and bond angles of polyhedra in directionally bonded systems, and bond lengths and icosahedral geometry in metallic systems, can be catalogued and compared with experiment. Likewise, one can examine directly IRO and LRO such as ring statistics in covalent structures and MRO, for example, the icosahedral variety, in metallic alloyed structures. Moreover, dynamic properties like ion diffusivities can be predicted as a function of temperature and pressure, the same applying to vibrational modes that determine the VDOS – not least the many-atom cooperative motion responsible for the boson peak.

6 Structural Heterogeneity in Glasses

The conceptual CRN and DRPHS models for glass structure [15, 16] are based on single-type polyhedra or atoms, respectively, and predict extended range order to be homogeneous everywhere. Because these models are constructed statically, not dynamically, DFs are also excluded. A geometric consequence of introducing more than one size of polyhedron or atom type is *microsegregation* in the packing of the minority component, first as clusters, which then coalesce into channels above the percolation limit (~20%). This evolution was originally predicted from the 2-D modified random network (MRN) model [9] and later from 3-D MD simulated structures [2].

Interestingly, a similar clustering is also evident in computer-simulated metallic glass structures, such as the metalloid P in the RMC model for $\text{Ni}_{0.8}\text{P}_{0.2}$ metallic glass, where this microsegregation can be seen threading through the close-packed Ni structure ([12] Figure 1).

For MRN structures (Figure 8), channels are defined by nonbridging oxygens (NBOs) resulting in silicons, for example, being surrounded by mixtures of BOs and NBOs, which can be readily identified by ^{29}Si MAS NMR [1, 28]. In aluminosilicate glasses, aluminums occupy tetrahedral sites AlO_4^{-1} [1] where the extra charge is compensated for by adjacent modifier cations like alkalis or alkaline earths. For fully compensated compositions, like those of feldspars, glasses, silicon, and aluminum tetrahedra are corner-shared via BOs, adopting a CRN-like geometry that is categorized as a compensated continuous random network (CCRN) [28]. Alkali channels have also been predicted in aluminosilicate melts and glasses, like the nepheline family ($\text{Na}_x\text{K}_{1-x}\text{AlSiO}_4$)

Figure 8 Microsegregation in network glasses. (a) Modified random network (MRN) used to model oxide glasses [9]. Cation modifier channels clearly seen percolating through the two-dimensional network, 3-D microsegregation later confirmed with MD methods [2]. (b) Isosurfaces delineating K^+ conducting pathways in MD simulated $K_2Si_2O_5$ disilicate glass, with cutaway showing adjacent interweaving modified silicate network. (c) Alkali channels in MD simulated aluminosilicate $Na_{0.25}K_{0.75}AlSiO_4$ [27]. (d) Ag^+ channels in the superionic glass $(AgI)_{0.6}-(Ag_2O-2B_2O_3)_{0.4}$ separated from anion borohalide pockets. *Source:* (a) Reproduced from [9] © (1985) Elsevier; (b) image courtesy Z. Zhou; (c) reproduced from [27] © (2017) Nature Publications; (d) reproduced from [10] © 2001 Institute of Physics.

(Figure 8), confirmed by MD modeling, which also reproduces the way the viscosity changes with composition [27].

Modifier channels were envisaged from the start as supporting ionic diffusion, such as that of alkali ions migrating through oxide glasses [28]. The use of isosurfaces to delineate channels (Figure 8) helps visualize the separation of mobile ions from the surrounding network. The presence of well-defined channels explains the additional FSDP observed, for example, in modified silicate glasses around $0.8 \text{ \AA}^{-1}$, which can be attributed to correlations between alkalis with a quasiperiodicity of about $8 \text{ \AA}$ [1]. Other evidence comes from EXAFS and MAS NMR experiments.

There is now much support for the idea of reconciling structural heterogeneity with transport properties [28]. For example, the mixed alkali effect, where the mixing of different mobile alkalis in the same glass drastically affects the mobility of both, can be understood in terms of the

segregation of alkalis packing *within* channels, diluting the diffusivity of each ([2], Chapter 4.6). The huge fall in the average ionic mobility with alkali mixing reduces the ionic conductivity of glass and increases its corrosion resistance and other related transport properties [28].

Fast-ion conducting glasses based on silver salts, like AgI dissolved in oxide and sulfide matrices, have unusually high ionic conductivities at ambient temperature, exceeding those of binary alkali silicates and borosilicates by three or four decades, making them attractive as possible electrolytes for solid-state batteries. For these systems RMC modeling has been interpreted in terms of the MRN and the high diffusivity of Ag^+ along percolating channels that are approximately one-dimensional (Figure 8). Like for conventional modified oxide glasses, the FSDP is often structured for fast-ion conducting glasses with Ag–Ag and anion–anion components, the former with a quasiperiodicity approaching $10 \text{ \AA}$. This is illustrated for $(AgI)_{0.6}-(Ag_2O-2B_2O_3)_{0.4}$ glass in

Figure 8 where the topology of ion transport channels can be clearly seen. As the AgI content increases, extending the composition range (and with it the ionic conductivity), the halide component “pushes apart” the remaining network, which also becomes more disordered. The FSDP is dominated by Ag–Ag quasiperiodicity so that this is the feature that correlates with superionic diffusivity within glass-forming compositions [10].

In these examples, structural heterogeneity is manifest both in the IRO related to the FSDP and topologically over LRO and beyond to embody the extended structure of glass.

7 Perspectives

For the future, the ideas about the extended structure of glass, introduced separately in this chapter, need eventually to be consolidated into a holistic description. This is implicit in the conceptual MRN, CRN, and DRPHS models [9, 13, 25] whose fixed geometries are infinitely perpetuated through rings of different sizes and modifier channels for insulating network glasses and through variations in icosahedra for densely packed metallic glasses. Nevertheless, for the last two decades of research, SRO, IRO, and LRO/MRO have been loosely defined in terms of static geometry between basic atomic building units, correlations between adjacent units, and more distant neighbors. This has created demarcations, often based on different experimental techniques, that avoids the central issue. The extended structure of glass should rather be seen as a continuous development from the microscopic atomic level through mesoscopic dimensions to the macroscopic scale relevant to applications.

The challenge in glass science is to associate, in a quantitative way, atomic structure with functionality [1, 3, 7]. In particular, heterogeneity is a common feature of functional glasses but is incompletely understood at the level of static structures. It has its antecedents in the rheology of the supercooled state and the dynamics of the glass transition. Empirical correlations have been reported, often controversially received, between the fragility m of supercooled liquids at the glass transition and solid-state properties such as Poisson’s ratio, between m and I_{BP} , and between m and $f(0,T)$ [1]. Underlying all these relationships is the role played by DFs, which increase in amplitude at the dynamic crossover $\sim 1.2T_g$ [26] and are frozen into the glassy state as α relaxation dynamics slow down. They appear to be central to nucleation processes, whether these are crystallization, phase separation, or polyamorphism. DFs have the dimensions of the acoustic wavelengths of the boson peak, which underscores, again, the cooperative nature of the many-atom

fast β dynamics in the condensation of glasses and their functionality.

Finally, the important technical drivers in meeting the challenge raised by the prospect of understanding the extended structure of glass as a predictor of functionality are the advances in experimental technology. First are those coming from light and particle beams in materials science – spallation neutron sources, coherent X-ray sources, electron nanobeams, and atomic-scale microscopy. These tools have already escalated in intensity and diversity in recent years, increasingly driven by the needs of the biosciences, where similar issues exist in handling complexity and aperiodicity on a grand scale. Second, and as important, are advances in high-performance computing and the visualization of big data sets. Year on year larger and larger simulations are reported, sizes for MD, currently reaching several million atoms, already on a length scale commensurate with DFs. *Ab initio* techniques, which are the most reliable for predicting functionality, necessarily lag behind, but are currently heading toward the thousand atom mark – all of which concurs with the forward thinking of Alder and Wainwright, over 50 years ago, that “the behaviour of systems of many interacting particles cannot, in general, be dealt with theoretically in an exact way [...] Since these difficulties are not conceptual but mathematical, high-speed computers are well-suited to deal with them” [29].

2.6

Structure of Chemically Complex Silicate Systems

Bjorn Mysen

Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC, USA

1 Introduction

Chemically complex silicate glasses and melts include natural magmatic liquids as well as many commercial glasses. Magmatic rocks sometimes also are used for commercial purposes with slight compositional adjustment made to optimize processes or material properties and reduce costs (e.g. rock wool, Chapter 9.3).

Glass families such as boro- and phosphosilicates are specifically dealt with in Chapters 7.6 and 7.9, respectively. The chemically complex glasses and melts considered here are mainly aluminosilicates with Si^{4+} and Al^{3+} as the main network-formers and alkali metals, alkaline earths, and Fe^{2+} the dominant network-modifiers. Their structure, properties, and structure/property relations can be described with the aid of information obtained with compositionally simpler unary, binary, and ternary compositions and composition joins (Figure 1). The principal composition variables are metal oxide/silica, alumina/silica, and types and proportions of metal cations with different electronic properties (see also [1]).

The structural environment changes when pressure during melting is sufficiently high to cause oxygen coordination changes of Al^{3+} and Si^{4+} (≥ 6 GPa). High-pressure data are so limited, however, that a survey will not be very informative and high-pressure industrial processes are virtually nonexistent. Pressure will not, therefore, be discussed here.

2 Glass and Melt Polymerization

The degree of polymerization of the aluminosilicate network affects most glass and melt properties. Melt

polymerization can be expressed as the proportion of nonbridging oxygen (NBO) per tetrahedrally coordinated cations (T), NBO/T . The NBO/T can be calculated from the chemical composition of a glass and melt, provided that types and proportions of network-forming cations are known. Then, $\text{NBO}/\text{T} = (2 \cdot \text{O} - 4 \cdot \text{T})/\text{T}$, where T and O are atomic proportions of tetrahedral cations and oxygen, respectively, and T is given a formal charge of 4 can be readily calculated.

The principal network-formers (tetrahedral cations) in complex glasses and melts are Si^{4+} and Al^{3+} . These will be discussed first.

2.1 SiO_2

In nature, the SiO_2 concentration in some cases can exceed 80 wt % although in the most common magma, basalt, the SiO_2 range is 45–55 wt %. By comparison, most commercial glasses have from 50 to 70 wt % SiO_2 contents (Table 1).

From the relatively small enthalpy, entropy, and volume of fusion (ΔH , ΔS , and ΔV) of crystalline SiO_2 polymorphs (see [2] for review of data), it may be inferred that silica melt and glass retain a three-dimensional structure of interconnected SiO_4 tetrahedra that exist in its crystalline polymorphs (quartz, tridymite, and cristobalite). From vibrational, X-ray, and NMR spectroscopic studies, one also concludes that the SiO_2 glass structure is essentially fully polymerized [3]. Vibrational spectroscopic spectra recorded at temperature above that of the glass transition of silica glass (1208°C) do not reveal significant structural differences between glass and supercooled liquid. There is an asymmetric distribution of intertetrahedral angles, ranging from ~ 120 to 180° (Figure 2) with a maximum between 145 and 155° [4]. A 145 – 155° Si–O–Si angle is that expected in a three-dimensionally interconnected SiO_2 glass structure

Figure 1 Compositional environment of complex silicate melts and glasses. Peralkaline denotes compositional range where there is excess metal cations (alkali metals + alkaline earths) over that necessary for charge-balance of tetrahedrally coordinated Al^{3+} . Meta-aluminous compositions are those where the proportion of alkali metals + alkaline earths is exactly equal to that needed for charge-balance of tetrahedrally coordinated Al^{3+} . Peraluminous compositions are those where there is excess Al^{3+} over that which can be charge-balanced with alkali metals + alkaline earths.

consisting predominantly of six-membered rings. The somewhat asymmetric Si—O—Si angle distribution (Figure 2) suggests that more than one exists in SiO_2 glass. Rings with three or four SiO_4 tetrahedra coexisting with six-membered rings are those most commonly suggested.

The coexistence of distinct structural units has important consequences because it has been invoked to account for the unusual properties of SiO_2 glass such as a room-temperature density maximum for glass quenched from temperatures near 1505°C . Besides, a density minimum is observed near 950°C for structurally relaxed glass. The anomalous pressure- and temperature-dependence of SiO_2 glass compressibility, with maxima near 3 GPa and 100 K, respectively, can also be modeled with two coexisting three-dimensional structures in SiO_2 glass.

2.2 Al_2O_3

The second most important network-forming component in complex aluminosilicate glasses and melts is Al_2O_3 (Table 1). Its concentration range in most natural magma and commercial applications (5–20 wt % Al_2O_3) can have profound influence on glass and melt properties compared with pure SiO_2 . These include better glass-forming ability of melts, improved durability, lower viscosity, and lower thermal expansion.

The type of metal cations serving to charge-balance tetrahedrally coordinated Al^{3+} is central to understanding the structural roles of Al^{3+} in silicate melts and glasses and, therefore, their physicochemical properties. Charge-balance commonly is achieved with alkali metals and alkaline earths (as in feldspar structures, for example). With an alkali metal, M^+ , one Al^{3+} can be charge-balanced provided that $X_{\text{M}^+} \geq X_{\text{Al}^{3+}}$, whereas for alkaline earths, the requirement is $0.5 X_{\text{M}^{2+}} \geq X_{\text{Al}^{3+}}$, where X_{M^+} , $X_{\text{Al}^{3+}}$, and $X_{\text{M}^{2+}}$ are atomic fractions of the respective cations.

The structural environment near alkalis and alkaline earths depends on whether these ions play a

Figure 2 Distribution of intertetrahedral angle, $\angle(\text{Si}-\text{O}-\text{Si})^\circ$, in SiO_2 glass from fitting of ^{29}Si MAS NMR spectra to an angle distribution function. Note that the maximum corresponds to that of cristobalite at its liquidus temperature (1723 °C), and is also similar to that obtained from X-ray diffraction of SiO_2 glass. A recent ^{17}O NMR two-dimensional dynamic angle study resulted in 147° [3]. These angle distributions are consistent with a SiO_2 glass structure comprising predominantly six-membered rings of three-dimensionally interconnected SiO_4 tetrahedra.

charge-balancing or a network-modifying role [5]. The type and proportion of charge-balancing cations also are important because of their different effect on the energetics of the O–Al bonds and, therefore, on glass and melt properties. This is seen, for example, in enthalpy of solution (Figure 3), viscosity, and also in melt and glass density, compressibility, and thermal expansion.

The glass structure along SiO_2 – MAIO_2 joins (M = alkali metal as charge-balancing cation – meta-aluminosilicate; see Figure 1) is a continuous evolution of the SiO_2 glass structure with substitution of Al^{3+} for Si^{4+} in tetrahedral coordination and with only a very small percentage or fraction of a percent of Al^{3+} in different structural roles. There is marginally more Al^{3+} in such roles in glasses along the SiO_2 – CaAl_2O_4 join [7].

The K^+ , Na^+ , and Ca^{2+} are the dominant charge-balancers in natural magmatic liquids (Figure 4). For melts and glasses with multiple potential cations for Al^{3+} charge-balance, thermodynamic data can be used to establish relative stability of aluminate complexes. There is near equal stability of $(\text{KAl})^{4+}$ and $(\text{NaAl})^{4+}$ charge-balance followed by $(\text{Ca}_{0.5}\text{Al})^{4+}$. In natural rocks, the proportion of Ca^{2+} relative to $(\text{Na}^+ + \text{K}^+)$ decreases with increasing SiO_2 concentration so that in rhyolite melt, for example, alkalis dominate over Ca^{2+} for

Figure 3 Energetics of Al,Si substitution along meta-aluminosilicate joins as a function of ionization potential, Z/r^2 , of metal cation that serves to charge-balance Al^{3+} in tetrahedral coordination (ionic radius, r , assumed that of six-coordinated metal cations – data from [6]). Heat of solution of glasses in molten lead borate solution is used as a measure of the substitution energetics. Simple and systematic relations with Z/r^2 are evident, but with distinct separation of relationships for cations with different charge-balancing cations. This difference stems from different substitution mechanisms of Al^{3+} for Si^{4+} depending on whether the charge-balance is accomplished with monovalent or divalent cations.

charge-balancing of Al^{3+} . For less silica-rich melts, the main charge-balancing cation is Ca^{2+} . For commercial glass such as glass wool, Na^+ is the principal charge-balancing cation for tetrahedral Al^{3+} , whereas in rock wool with a composition more akin to natural basalt (Table 1; see also [1], chapter 18), alkali metals and Ca^{2+} serve to charge-balance Al^{3+} together. Somewhat similar structural features can be found in the glass containment of incinerated household waste.

3 Metal Oxide–SiO₂ Systems

3.1 General Remarks

In order to characterize the structure of depolymerized, chemically complex aluminosilicate glasses and melts (Figure 1), it is first necessary to describe the structure of simple binary metal oxide–silica compositions. With this information, one can then consider multicomponent metal oxide silicate and aluminosilicate glasses and melts.

The metal oxides in multicomponent metal oxide–silica systems usually are K_2O , Na_2O , CaO , and MgO . In Al-free silicate glasses such as window and container glass, for example, these oxides serve only as

Figure 4 Summary of distribution of charge-balancing cations ($\text{Na}^+ + \text{K}^+$ and Ca^{2+}) in natural magmatic liquids of basalt and rhyolite melt compositions as a function of the NBO/T of the melts. The summary was developed from chemical data in <http://Earthchem.org>. This web site contains a compilation of analyses of rocks in the published literature, where the individual rock names are those given in the source of the database. As seen in Figure 5, for each of these types of rocks, the NBO/T of their melts comprises a wide range. See Table 1 for average compositions of basalt and rhyolite.

network-modifiers. Glass used in television and computer monitors and in optical fibers comprises additional network-modifying cations including rare earths, large alkaline earths (Sr^{2+} and Ba^{2+}) and, sometimes, transition metals. In natural magmatic liquids, these cations can serve both as network-modifiers and to charge-balance Al^{3+} in fourfold oxygen coordination as described in Section 2.2. Similar compositions and structural environments can be found in glass and rock wool, E glass, and Vycor.

The properties and behavior of SiO_2 in metal oxide silicate melts and glasses differ somewhat from those of pure silica glass and melt. The partial molar volume of this component is slightly smaller ($26.8 \text{ cm}^3/\text{mol}$) than

the volume of pure SiO_2 ($27.3 \text{ cm}^3/\text{mol}$) because some of the oxygen in these glasses and melts are nonbridging (NBO) and the partial molar volume of NBO is slightly less than that of bridging oxygen. In metal oxide silicate, the partial molar volume of SiO_2 is independent of composition, however, over wide composition range [8]. Systematic relations between metal/silicon ratio can also be seen in other physical and chemical properties such as viscosity, conductivity, thermal expansion, and compressibility of glasses and melts [1].

In ternary and more complex metal oxide silica melts, the values of most properties cannot be described as linear combinations of the endmembers (*mixed alkali effect*). For example, window glass, which is essentially a mixture of Ca- and Na-silicate components, is in this category. This behavior is related to the steric effects that govern metal cation ordering among different NBO in ternary and more complex metal oxide- SiO_2 glasses and melts. Ordering affects configurational and mixing properties and, therefore, rheological and thermodynamic properties. The greater the contrast in electronic properties such as their electrical charge and ionic radius of the network-modifying cations, the greater the effect of mixing on melt and glass properties. This ultimately leads to liquid immiscibility in SiO_2 -rich metal oxide- SiO_2 melts. In fact, at given temperature the width of the immiscibility gap is a positive function, Z/r^2 (Z = formal electrical charge, r = ionic radius), of the metal cation.

3.2 Structure

Structural characterization of simple and complex metal oxide silicate glasses and melts can be expressed in terms of nonbridging oxygen, NBO, per tetrahedrally coordinated cation, T (Chapter 2.4). The NBO/T-values of commercial glasses range from about 0.2–0.3 (for Pyrex glass, for example) to values greater than 3.0 for some slags (Chapter 7.4). The NBO/T of typical window glass is about 0.8, which is similar to those of rock wool. In nature, the NBO/T-values of melts from individual rock types fall within relatively broad ranges (Figure 5). In general, there is a negative correlation between the NBO/T-value and the SiO_2 concentration.

The distribution of network-modifying cations in complex systems is linked to both their alkali metal/alkaline earth ratio and the types of metal cations available for charge-balance of tetrahedrally coordinated Al^{3+} . For the most part, the network-modifying cations in natural magma are alkaline earths because their Na + K components charge-balance tetrahedrally coordinated Al^{3+} . Among the network-modifying cations, Mg^{2+} is exclusively a network-modifier, whereas Ca^{2+} is used both to charge-balance Al^{3+} and to serve as a network-modifier (Figure 6).

Figure 5 Calculated distribution of NBO/T-values of major groups of natural magma compositions derived from the database, <http://Earthchem.org>. Also shown (arrows) are approximate NBO/T-values for Pyrex glass and glass wool. Average basalt and rhyolite compositions are shown in Figure 4.

Figure 6 Distribution of network-modifying cations (Na⁺, Ca²⁺, and Mg²⁺) in natural magmatic liquids of basalt and rhyolite melt compositions as a function of the NBO/T of the melts. The summary was developed from chemical data in <http://Earthchem.org>.

3.3 Speciation, Cation Mixing, and Ordering

The NBOs in glasses and melts are not equivalent energetically. Instead, the structure of metal oxide–SiO₂ glass and its precursor melt is described in terms of a small number of distinct coexisting silicate structural units commonly described as Q^n -species with $n = 0, 1, 2, 3$, and 4 where n is the number of bridging oxygen (Chapter 2.4). The overall degree of polymerization, NBO/T, is related to Q^n -species abundance:

$$\frac{\text{NBO}}{\text{T}} = \sum_{n=0}^{n=4} (n-4)X_{Q^n}, \quad (1)$$

where X_{Q^n} is the mol fraction of the Q^n -species and n is the number of bridging oxygen in the individual Q^n -species. The NBO/T-parameter itself does not distinguish between different types of NBO.

The abundance of individual Q^n -species changes with metal oxide/SiO₂ ratio of the material (Figure 7). In simple binary metal oxide–silica melts, the abundance of Q^3 , Q^2 , and Q^1 species reaches maximum values at stoichiometries near NBO/Si = 1, 2, and 3, respectively, and decreases on both sides of these maxima. Orthosilicate compositions comprise both Q^1 and Q^0 species with free oxygen compensating for the presence of the polymerized Q^1 structure. The Q^n -species abundances also are affected by the ionization potential, Z/r^2 (Z : formal electrical charge, r : ionic radius), of the metal cation (Figure 7) because steric hindrance near the NBO governs how individual metal cations will distribute themselves among the Q^n -species. The ordering of alkalis and alkaline earths among energetically nonequivalent NBO in different Q^n -species in multicomponent compositions also aids in the explanation of the mixed alkali effect. For comparison, in crystalline metal oxide–SiO₂ systems, analogous steric hindrance effect instead limits the minimum metal oxide/SiO₂ ratio of the crystalline materials below which crystalline compounds are not stable [9].

In the much more chemically complex natural magmatic liquids, Q^n -species distributions resemble those observed for binary metal oxide glasses and melts [10]. The influence of individual network-modifying cations is difficult to establish, however, because of wide ranges of compensating effects on structure from the large number of different network-modifying cations.

Whether in simple binary metal oxide silicates or more complex systems, the equilibrium constant for the principal expression that describes the equilibria among the Q^n -species, $2Q^n \rightleftharpoons Q^{n-1} + Q^{n+1}$ (see Chapter 2.4), is positively correlated with Z/r^2 at least for systems for which $n = 3$ in the aforementioned reaction to yield $2Q^3 \rightleftharpoons Q^2 + Q^4$ (Figure 8). The enthalpy change of the latter reaction at temperatures above the glass transition is also a positive function of the Z/r^2 of the metal cation and is more sensitive to Z/r^2 of the more polymerized (lower bulk

Figure 8 Enthalpy change, ΔH , for the disproportionation equilibrium, $2Q^n \rightleftharpoons Q^{n-1} + Q^{n+1}$, $n = 3$, as a function of ionization potential of alkali cation for two series of alkali metal (M) silicate compositions. In these systems, $M/Si = NBO/Si$ assuming all Si^{4+} is in tetrahedral coordination in the glasses. The ΔH is derived from temperature-dependent equilibrium constant at temperatures above the glass transition and assuming that mol fraction of Q^n -species equals their activity. Note that the ΔH -value increases with increasingly polymerized melts probably as a result of increasingly nonideal mixing of the Q^n -species. (Source: Modified after [8].)

NBO/Si-value) silicate melt (Figure 8). This relationship obtains because steric hindrance near NBOs diminishes with decreasing average values of n of the Q^n -species.

4 Aluminum and Aluminate

Characterization of the structural roles of Al^{3+} in aluminosilicate compositions is central to understanding their

Figure 7 Abundance evolution (mol %) of Q^2 , Q^3 , and Q^4 species in alkali silicate glasses as a function of their NBO/Si-values of compositions as indicated in diagrams. For alkali silicate glasses, the metal/silicon ratio equals the NBO/Si, provided that all Si^{4+} is in tetrahedral coordination. The ionization potential, Z/r^2 , of K^+ and Li^+ is 0.46 and 1.49, respectively, assuming sixfold coordination of oxygen around the alkali metal. The curves for Na_2O-SiO_2 (Z/r^2 of Na^+ : 0.8) fall in between those of Li_2O-SiO_2 and K_2O-SiO_2 .

properties. The role of Al^{3+} can vary from simple substitution for Si^{4+} in the network of interconnected aluminosilicate tetrahedra to more complex environments where Al, Si substitution is restricted to only some of the Q^n -species. The latter feature is important because most chemically complex compositions are depolymerized ($NBO/T > 0$) so that multiple Q^n -species will coexist.

4.1 Al^{3+} and Q^n -Species

Where there is excess alkali metal or alkaline earths over that needed for charge-balance of Al^{3+} in tetrahedral coordination, Al^{3+} may be distributed among the various Q^n -species. However, this distribution is not random and Al^{3+} dominantly is in Q^4 -species. Coexisting, less polymerized Q^n -species are essentially devoid of Al^{3+} . This situation reflects the tendency of Al^{3+} to substitute for Si^{4+} in SiO_4 tetrahedra with the smallest intertetrahedral angle, which is found in Q^4 -species.

It follows that the equilibrium constant for the reaction, $2Q^3 \rightleftharpoons Q^2 + Q^4$, is positively correlated with $Al/(Al + Si)$ of the glass and melt. For peralkaline alkali aluminosilicate melts (see Figure 1) at temperatures above their glass transition, the temperature-dependent equilibrium constant yields ΔH -values increasing from near 0 to about 40 kJ/mol in the $Al/(Al + Si) = 0-0.4$ range. Fewer experimental data exist for peralkaline alkaline earth aluminosilicate glasses.

In chemically complex environments with both alkalis and alkaline earths present, the alkali metals associate with the Al^{3+} in the Q^4 species, whereas alkaline earths tend to bond with NBO in depolymerized species [10]. It follows, therefore, that for systems such as natural magmatic

liquids, the Q^n -distribution is controlled for the most part by the rules that govern alkaline earth compositions.

This can be illustrated with the use of experimental data from ternary aluminosilicates to model the properties of chemically more complex systems. For example, the physicochemical properties of aluminosilicate glasses and melts, which vary with (Si,Al)—O bond energy, can be related qualitatively, and sometimes semi-quantitatively, to the Al/(Al + Si) ratio and to the electronic properties of charge-balancing cation because the bond energy varies with these same variables. The viscosity and activation energy of viscous flow of melts along meta-aluminosilicate joins, which are essentially fully polymerized, follow such simple evolutions within temperature intervals where the temperature-dependent viscosity is approximately Arrhenian (Figure 9). In contrast, the viscosity of peralkaline aluminosilicate melts does not show this effect of Al/(Al + Si) and actually may have a minimum at intermediate Al/(Al + Si)-values (Figure 9). This difference is because of a combination of weakening of (Si,Al)—O bonds in Q^4 -species with increasing Al/(Al + Si) and changing Q^n -species abundance with increasing Al/(Al + Si).

Figure 9 Activation energy of viscous flow of aluminosilicate melts along the NaAlO₂—SiO₂ (nominal NBO/T = 0) (meta-aluminosilicate) join (closed squares) and Na₂Si₂O₅—Na₂(NaAl)₂O₅ (nominal NBO/T = 0.5) (peralkaline aluminosilicate) calculated with the assumption of Arrhenian viscosity of the melts. As discussed in the text, NaAlO₂—SiO₂ melts and glasses do have a small fraction of a percent nonbridging oxygen, but are essentially pure Q^4 with Al-substitution for Si. Melts and glasses on the Na₂Si₂O₅—Na₂(NaAl)₂O₅ join, on the other hand, comprise Q^2 , Q^3 , and Q^4 species with essentially all Al³⁺ in substitution for Si⁴⁺ in the Q^4 species thus weakening the (Si,Al)—O bridging oxygen bonds in this specie. This, in turn, lowers the activation energy as for the NaAlO₂—SiO₂ melts and glasses. However, because of Al-preference, the proportions of Q^n -species change so that Q^4 abundance increases, thus countering the effect of the Al,Si-substitution. These two mechanisms give rise to the minimum activation energy values at intermediate Al/(Al + Si) values.

The compressibility and thermal expansion of alkali aluminosilicate melts are also correlated with Al/(Al + Si) because the intertetrahedral (Si,Al)—O—(Si,Al) angle is itself more compressible and expandable with increasing Al/(Al + Si). In alkaline earth aluminosilicate systems, however, the opposite relations exist because Ca-charge-balanced Al³⁺ causes the (Si,Al)—O—(Si,Al) bonds to stiffen. In other words, the compressibility and thermal expansion of such aluminosilicate melts decreases with increasing Al/(Al + Si).

Among the main groups of natural magmatic liquids (basalt, andesite, and rhyolite), the proportion of alkaline earths/alkali metals in charge-balancing roles decreases in the same order. This means that basaltic melts are less compressible and show smaller thermal expansion than more silica-rich melts such as rhyolite. Furthermore, the viscosity of basalt melt is less sensitive to Al/(Al + Si) than more silica-rich magma, which have a higher proportion of alkali-charge-balanced Al³⁺ in tetrahedral coordination.

5 Ferric and Ferrous Iron

Iron is found in three redox states, Fe⁰, Fe²⁺, and Fe³⁺, but only the last two can enter the structure of silicate compositions in significant amounts. In this environment, the proportions of Fe²⁺ and Fe³⁺ vary with bulk chemical composition of glasses and melts, temperature, pressure, and redox conditions during equilibration of precursor melt. In magmatic liquids, the Fe³⁺/ΣFe ranges from essentially 0 to 1 (Figure 10) in such a way that this redox ratio has been employed to estimate the activity of oxygen and, therefore, oxygen budgets during formation and evolution of earth materials and, indeed, the Earth, itself.

5.1 Redox Relations of Iron

Equilibria between Fe³⁺ and Fe²⁺ in silicate melt and glass include interaction with oxygen in the structure. Conversely, variations in redox behavior of iron oxides affect the silicate melt structure. From the simple relationship,

where O²⁻ is the link to the silicate structure, the relationship between redox ratio and oxygen fugacity provides a measure of the activity coefficient ratio of Fe³⁺ and Fe²⁺, $g_{\text{Fe}^{3+}}/g_{\text{Fe}^{2+}}$. This ratio often is about 1, but does depend on silicate polymerization (Figure 11). The redox ratio also varies with Al/(Al + Si) and the electronic properties of the metal cations. It increases with Al/(Al + Si) and NBO/T. The redox ratio also increases the more electro-positive the network-modifying cation. This means, for example, that the Fe³⁺/Fe²⁺ of alkali silicate melts is

Figure 10 Distribution of redox ratio of iron ($\text{Fe}^{3+}/\Sigma\text{Fe}$) among various common rock types. Database: <http://Georock.org>. Examples of average compositions of basalt, andesite, and rhyolite are given in Figures 5 and 6.

greater than that of alkaline earth silicate melts at the same temperature (pressure) and redox conditions.

5.2 Structural Roles of Fe^{3+} and Fe^{2+}

It is sometimes assumed that Al^{3+} and Fe^{3+} occupy similar structural positions in silicate melts and glasses because of their common nominal charge and somewhat similar ionic radii. But this assumption is not necessarily warranted because Al^{3+} is dominantly in fourfold coordination in silicate crystals, whereas for the most part Fe^{3+} is in sixfold coordination with oxygen although there are exceptions to this general statement.

In silicate glasses and melts oxygen coordination numbers vary with bulk chemical composition, total iron content, temperature, and redox conditions that existed

Figure 11 Activity coefficient ratio of Fe^{2+} and Fe^{3+} in CaO-SiO_2 glasses formed by quenching from melt after equilibration at 1600°C with different oxygen fugacity. The NBO/Si -values in this figure were calculated from the Ca/Si ratio. From the relationship to oxygen fugacity, any deviation of the concentration ratio, $\text{Fe}^{2+}/\text{Fe}^{3+}$, was ascribed to changes in the activity coefficient ratio, $g_{\text{Fe}^{2+}}/g_{\text{Fe}^{3+}}$, because $(g_{\text{Fe}^{2+}}/g_{\text{Fe}^{3+}})(\text{Fe}^{2+}/\text{Fe}^{3+}) = 0.25$.

during precursor melting. The $\text{Fe}^{3+}\text{-O}$ bond distance of ferrisilicate glass is often used as an indicator of oxygen coordination number. For example, increasing iron content in Al -free silicates results in increasing $\text{Fe}^{3+}\text{-O}$ distance, which may be consistent with a transformation from fourfold to sixfold coordination.

Mössbauer spectroscopy of glasses is an analytical tool with which both redox ratio of iron and coordination of Fe^{3+} and Fe^{2+} can be determined (Chapter 2.2). In alkali ferrisilicate melts equilibrated with air, Fe^{3+} typically is in fourfold coordination with oxygen. However, by replacing Na^+ with more electronegative metals, the oxygen tetrahedra surrounding Fe^{3+} become increasingly distorted with an eventual changes to higher oxygen coordination numbers. As a result, in complex aluminosilicate compositions containing both alkalis and alkaline earths it is not unusual that Fe^{3+} exists in more than one coordination state.

Most evidence suggests that Fe^{3+} in fourfold coordination forms oxygen tetrahedra that are isolated from those of Si^{4+} and Al^{3+} . Furthermore, when both alkali and alkaline earths are potential charge-balancing cations in complex systems, alkali metals tend to associate with Al^{3+} , whereas alkaline earths serve to charge-balance Fe^{3+} in tetrahedral coordination with oxygen. This means, for example, that if a rhyolite and a basalt melt equilibrated at the same oxygen fugacity, temperature, and pressure, the iron would be more oxidized in the rhyolite than in the basalt melt.

At least in FeO—SiO₂ systems the Fe²⁺—O distances are consistent with sixfold coordination although it has also been suggested that the oxygen coordination number of Fe²⁺ might be closer to 4 than to 6. Results from ⁵⁷Fe Mössbauer resonant absorption spectroscopy of iron-bearing glasses offer additional aid to distinguish between possible oxygen coordination numbers of ferrous iron (4, 5, and 6).

5.3 Structure–Property Relations

The physical properties of iron-bearing silicate melts and glasses are less well known than for iron-free materials. Viscosity and volume data can nonetheless be rationalized in structural terms.

The partial molar volumes of FeO and Fe₂O₃, $\bar{V}_{\text{FeO}}$ and $\bar{V}_{\text{FeO}_{1.5}}$, are sensitive to oxygen coordination. The $\bar{V}_{\text{FeO}}$ in glass (between about 13 and 14 cm³/mol) resembles the molar volume of crystalline wüstite (FeO), which suggests that Fe²⁺ is sixfold coordinated in glasses. The $\bar{V}_{\text{FeO}_{1.5}}$ -values are more variable, however, and depend on composition. For example, in SiO₂—NaFeO₂ glasses formed by quenching from melt equilibrated with air (and with Fe³⁺/SFe > 0.95), $\bar{V}_{\text{FeO}_{1.5}}$ is between 20 and 21 cm³/mol (as FeO_{1.5}), whereas for equivalent Ca-ferrisilicate melt, $\bar{V}_{\text{FeO}_{1.5}} = 13\text{--}15$ cm³/mol [11]. These latter volumes are those expected with Fe³⁺ in tetrahedral and octahedral coordination, respectively.

The viscosity of iron-bearing silicates depends on both redox state of iron and on the coordination state of Fe²⁺ and Fe³⁺. For example, with Fe³⁺ in fourfold coordination and Fe²⁺ in sixfold coordination with oxygen, melt viscosity increases systematically with increasing Fe³⁺/SFe because silicate polymerization also increases with increasing Fe³⁺/SFe [12]. When both Fe³⁺ and Fe²⁺ are surrounded by octahedral oxygen ligands, this relationship is reversed. Given that the redox ratio in basaltic melts normally is considerably lower and the oxygen coordination number around Fe³⁺ higher than in more silicate rich melts (andesite and rhyolite, for example), decreasing Fe³⁺/Fe²⁺ in the former may result in increased melt viscosity, whereas the opposite trend obtains for the latter.

6 Minor Components in Silicate Glasses and Melts

Minor components such as TiO₂ and P₂O₅ are important in natural and commercial glasses, including optical fibers and glass wool insulating materials. The structural behavior of P⁵⁺ in silicate glasses and melts is fairly well known, whereas that of Ti⁴⁺ remains more controversial, perhaps

because the oxygen coordination environment surrounding Ti⁴⁺ may be a composition-dependent variable.

6.1 Phosphorus Substitution for Silicon

In P₂O₅ glass, the P—O bridging bond distance (1.60 Å) is nearly identical to the Si—O distance in SiO₂ glass (1.62 Å). Additionally, there is a second double-bonded and shorter (1.43 Å) P=O bond. These structural features remain for glasses in the P₂O₅—SiO₂ system. In the latter, Si—O—P bridges can also be detected.

Phosphorus in metal oxide silicate and aluminosilicate glasses and melts is dissolved by formation of phosphate (PO₄) groups. Their degree of polymerization can be derived from ³¹P NMR spectra as a function of metal oxide/P₂O₅ ratio [13] in a way similar to Qⁿ-species determinations in metal oxide—SiO₂ glasses (see also Chapter 2.4 and Section 3.1). In addition, there are minor contributions from Si—O—P linkages. Mixed alumino-silico phosphate complexes are more common (Chapter 2.4).

6.2 Multiple Roles of Ti⁴⁺

The ionic radius of Ti⁴⁺ is nearly twice that of Si⁴⁺. It is not surprising, therefore, that Ti⁴⁺ in crystalline materials commonly occupies sixfold coordination, whereas Si⁴⁺ is in tetrahedral coordination. In glasses and melts, on the other hand, the structural behavior of Ti⁴⁺ is more complex. From partial molar volume of TiO₂, $\bar{V}_{\text{TiO}_2}$ -values near 30 cm³/mol in alkali silicate and $\bar{V}_{\text{TiO}_2}$ to be ≤25 cm³/mol in alkaline earth silicate point to different structural behavior governed by the nature of the metal cations [8].

Raman and XANES spectroscopic data of SiO₂—TiO₂ glasses suggest Ti⁴⁺ in five- and sixfold coordination with oxygen at low concentrations (<3 mol % TiO₂), whereas in more concentrated solution, Ti⁴⁺ is surrounded by four oxygens. However, it also has been suggested from X-ray and neutron diffraction data that fourfold coordination dominates at low TiO₂ concentrations in alkali silicate glasses, whereas fivefold coordination is more important at higher concentrations. The latter conclusions are in qualitative agreement with inferences drawn from Raman spectra of alkali aluminosilicate glasses. In aluminosilicate glasses, the Al/(Al + Si) ratio also affects the oxygen coordination number around Ti⁴⁺.

7 Perspectives

We are poised to advance our understanding of silicate compositions from empirical modeling, based on current understanding of property–structure relationships and

simple oxide-based descriptions, to direct determination of the structure of complex systems. The anionic structural backbone is established. As indicated by the first steps taken in this direction, quantitative understanding of structural variations with composition and intrinsic variables is possible. Moreover, with increased miniaturization and micro-processing, measurements of glass and melt properties with samples under the conditions of interest are now feasible. It will also be possible to track and characterize structurally the kinetics of transformations, to quantify glass-forming processes, and, likely, to engineer properties of glasses on the basis of our rapidly advancing enhanced understanding of structure–property relations.

Topological Constraint Theory of Inorganic Glasses

Prabhat K Gupta

The Ohio State University, Columbus, OH, USA

1 Introduction

Compositional innovation has been the bedrock of glass R&D for more than a century. Two questions always come up when searching for a new composition: Will the material be easy to form into glass from the liquid and will its properties have the values desired for the application considered? This set of properties includes not only those of the finished glass product (mechanical, for example) but also those necessary for successful processing (such as melt viscosity and glass transition temperature, T_g). In principle, the topological constraint theory (TCT) can aid in providing answers to both of these questions.

Historically, TCT grew along two distinct paths, both starting at about the same time in the late 1970s. The more widely known view, termed the *bond constraint theory* (BCT), was formulated in 1979 by Phillips [1] and is most useful for *chemically disordered* covalent systems such as chalcogenides. The other view applies to *chemically ordered* systems such as oxide glasses whose structure, *à la* Zachariasen ([2], Chapters 2.1 and 3.1), consists of topologically disordered extended networks of corner-sharing rigid polyhedra. This view was developed by Cooper [3] in 1978 for two-dimensional networks and later extended to three-dimensional networks by Gupta and Cooper [4]. We refer to this view as the *polyhedral constraint theory* (PCT).

During the early development, constraints were counted as either intact (=1) or broken (= 0) and temperature (T) played no role. In 1993 [5] (and in more detail in 1999 [6]), Gupta introduced the concept of temperature-dependence of bond constraints. In 2009, Gupta and

Mauro applied the T -dependent BCT to rationalize the composition (x) dependence of the glass transition temperature $T_g(x)$ in binary chalcogenide [7] and in binary oxide systems [8]. Later, Bauchy and Micoulaut [9] validated the phenomenology of T -dependent bond constraints with molecular dynamics (MD) simulations.

With growing interest in TCT, much effort has been and is being invested in applying it to model the composition dependence of a variety of properties in glassy systems. The most successful thus far has been the work of Mauro and colleagues [10] for the composition dependence of the room-temperature hardness of oxide glass systems. Not being a comprehensive review, however, the present chapter does not include these recent applications. It is organized as follows: an introduction to TCT is presented in the Section 2. It establishes key definitions and terminology and outlines the underlying conceptual framework. In Section 3, elements of PCT and some of its applications to oxide glass-forming systems are presented. Section 4 does the same for BCT with examples from chalcogenide systems. In Section 5, we discuss the phenomenology of the temperature dependence of constraints – a development that has generated much excitement owing to its remarkable ability to model variations of properties with composition. Some fundamental issues associated with TCT are discussed in Section 6 along with suggestions for possible ways to embed the TCT phenomenology within the general framework of the potential energy landscape (PEL) of liquids and glasses.

Not many comprehensive reviews of TCT are available in the literature. Early on, Phillips [11] published an introductory paper on BCT entitled “The Physics of Glass.” Thorpe [12] provided an account of the early developments of the rigidity percolation theory. Gupta [5] reviewed the PCT formalism in 1993 and later more extensively in 1999 [6]. Recently, Naumis and

Reviewers: P. Lucas, Materials Science and Engineering, University of Arizona, Tucson, AZ, USA

J. C. Mauro, Materials Science and Engineering, The Pennsylvania State University, PA 16802, USA

Romero-Arias [13] have reviewed the physics of the constraint theory, its connection with thermodynamics and with glass transition. More recently, Mauro [14] has published an excellent introduction on TCT.

List of Acronyms

TCT	topological constraint theory
BCT	bond constraint theory
PCT	polyhedral constraint theory
PEL	potential energy landscape
TD	topologically disordered

2 Concepts of the Topological Constraint Theory

Network-based concepts enter naturally in TCT, which treats a glass-forming system as an atomic network where atoms constitute the nodes (or vertices) and atomic interactions (i.e. chemical bonds) constitute the edges (or linkages) of the network. The properties of an atomic network depend both on its chemistry (how atoms of different species are placed on its nodes) and on its topology (how various nodes are interconnected without regard for the nature of atoms).

2.1 Network Chemistry

2.1.1 Composition of an Atomic Network

When a network contains only one kind of atom (i.e. the network is chemically homogeneous), it is called one component (or unary). Networks are termed binary when they contain only two kinds of atoms, and multicomponent if three or more distinct atoms are present. The (molar) fractions $\{x_i\}$ of atoms of the different components specify the average chemical composition of a network. In this paper, we discuss only unary or binary networks of type $A_xB_{(1-x)}$, where x represents the mole fraction of A atoms.

2.1.2 Chemical Order and Disorder

For a given x , the arrangement of A and B atoms on the vertices of a network determines the nature of the chemical order present. Often, for networks having compound-like compositions, $A_C B_V$ (where C and V are integers), the arrangement of two types of atoms is well defined: every A atom is coordinated by a number, V , of B atoms. Similarly each B atom is coordinated by another number, C , of A atoms. Such networks with well-defined chemical arrangement are called *chemically ordered*. In these networks, linear bonds exist only

between dissimilar atoms (i.e. heteropolar bonds). A prime example of such networks is that of silica (SiO_2): each silicon is coordinated by four oxygens ($V = 4$) and each O is linked to two silicons ($C = 2$).

Not all glasses can be chemically ordered as this state can be achieved only for some definite stoichiometries. Noncompound-like compositions are thus necessarily disordered. A signature of chemical disorder is the presence of homopolar bonds (between similar atoms). Even compound-like compositions can be chemically disordered in covalent systems because of the presence of a significant fraction of such homopolar bonds: an example is GeSe_2 [15].

2.1.3 Atomic Interactions and Chemical Bonds

Bonds constituting the edges of an atomic network represent simple mappings of atomic interaction potentials among the constituent atoms. For the purpose of TCT:

- Pair interactions are mapped into narrow potential wells, forming *linear bonds* of fixed length between neighbors. The tails of pair interaction potentials are ignored. Whereas this assumption is reasonable for short-range interactions, its validity is questionable for long-range coulombic potential, especially in BCT.
- Among many-body interactions, only triplet interactions are retained. They, together with next-nearest neighbor pair interactions, form the *angular bonds* at the vertices. Whereas angular constraints are important in BCT, they do not play any direct role in the PCT.

2.1.4 Structural Units in Chemically Ordered Networks

In a binary chemically ordered network, each A atom is coordinated by exactly the same number (V) of B atoms. Hence, the network can be viewed as made up of well-defined polyhedral (AB_V) structural units having an A atom in the center and a B atom at each vertex (i.e. corner). Further, C such structural units are connected in the network to each B atom. The chemical formula of the structural unit, $AB_{(V/C)}$, is therefore the same as that of the network as a whole.

2.2 Network Topology

For topological considerations, an atomic network is treated as if the observer is “chemically blind.” In other words, the network is considered simply as a combination of vertices and edges disregarding the nature of the atoms occupying the vertices. Thus, topology refers only to how the nodes are interconnected in a network.

Local (or short-range) topology at the i th vertex is described by the number (r_i) of edges shared by that

vertex (i.e. the vertex coordination number). A vertex having $r_i = 1$ is called non-bridging or dangling. Vertices with $r_i > 1$ are called bridging (or network-forming). When r_i is the same for all vertices, the network is called regular. Otherwise, it is irregular. For an irregular network, the average vertex coordination number, r , also called the *connectivity*, provides a measure of its short-range topology. Note that, in chemically ordered networks, r is related to the two coordination numbers V and C by

$$r = \frac{2CV}{(C + V)}. \quad (1)$$

The intermediate-range topology of a network is characterized by its ring-size distribution so that it, for instance, depends on whether neighboring structural units share edges or corners. By definition, noncrystalline networks have no long-range topological order. For this reason, they are termed *topologically disordered* (TD) networks [4].

2.3 Bond Constraints

The edges of a network represented by linear bonds constitute linear constraints on the coordinates of the vertices. In atomic networks, angular bonds give rise to additional constraints at the vertices. The linear and angular constraints, together, are called bond constraints. Since an angular constraint can be viewed simply as the result of an additional cross-linear bond between next-nearest neighbors, the linear and angular constraints carry equal weights. In other words, during constraint counting, one angular constraint and one linear constraint add up to two constraints.

It is important to distinguish between independent and dependent (or redundant) constraints. Constraints in a network that do not change its deformation behavior are called dependent. Consider, for example, a finite planar network of four nodes situated at the corners of a square (Figure 1) for which the sides constitute four linear constraints. If these are the only constraints present, the network is *floppy* (i.e. it can be deformed). When a diagonal constraint is added, however, the network becomes *rigid*. When a second diagonal is added as the sixth constraint, no further change occurs in the deformation behavior of the network – it remains rigid. The sixth constraint, in this example, is therefore a dependent constraint. In TCT, it is important to count only the independent constraints and to exclude the dependent. To determine whether a constraint is dependent or not can be a challenging task. Owing to the presence of long-range topological order, crystalline networks contain a significant number of dependent constraints.

Figure 1 Deformation of a finite network of four nodes. Lines represent linear constraints. Top: floppy network (hypostatic, $f > 0$) with only four constraints originating from the edges. Middle: addition of a diagonal constraint makes the network rigid (isostatic with $f = 0$). Bottom: addition of a second, dependent diagonal constraint does not change the rigidity of the network.

Whereas one has to be extremely careful in applying constraint theory to crystals, this is fortunately not the case in noncrystalline TD networks.

2.4 Degrees of Freedom and the Network Deformation Modes

Without constraints (as, for example, in an ideal gas), each atom has d coordinate degrees of freedom where d is the dimension of the network. As constraints are added at a vertex, its coordinate degrees of freedom decrease. If n is the average number of independent constraints per vertex, then the average degrees of freedom per vertex, f , in a network is given by

$$f = d - n. \quad (2)$$

If $n < d$, then f is positive and the network can deform without expenditure of energy. Such a network is termed “floppy” (or hypostatic) and has exactly f floppy (soft or low frequency) modes per vertex. The number of degrees of freedom decreases as n increases. When $n > d$, the network is over-constrained and is termed “stressed-rigid” (or hyperstatic). The excess $(n - d)$ constraints in a stressed-rigid network are dependent if such a network exists. The transition from floppy to stressed-rigid takes place at $n = d$ (i.e. at $f = 0$), which marks the disappearance of floppy modes and the onset of network rigidity. Such a network is called *isostatic* (Figure 1).

In a floppy network, there may exist finite-size rigid inclusions (small group of atoms interconnected in a rigid manner) that are embedded in a floppy matrix. The average size of such rigid clusters grows as n increases till the rigid clusters begin to percolate, causing a transition from a floppy into a rigid network at $n = d$. Similarly, when a network is stressed-rigid ($n > d$), it may contain floppy clusters in a rigid matrix. The average size of these floppy clusters grows as n is reduced so that at $n = d$, the floppy clusters begin to percolate making the entire network floppy. Thus, a network undergoes a rigidity percolation transition at $f = 0$. This basic idea is at the heart of most TCT applications because n can vary with changes in both temperature and composition. In other words, since $n = n(T, x)$, the isostatic boundary in a T - x phase diagram is described by $n(T, x) = d$.

3 Polyhedral Constraint Theory

As mentioned before, PCT considers only chemically ordered networks which, according to Zachariasen [2], are TD networks of structural units made up of corner-sharing rigid polyhedra. In such networks, it is convenient to treat the shared corners of the polyhedra as the vertices and the polyhedral structural units as links. The rigidity of a network then arises from the rigidity of the structural units as well as from the vertex-connectivity condition (i.e. the fact that all corners of polyhedral units are shared among a certain number of units). These constraints resulting from the rigidity of structural units and connectivity are termed *polyhedral constraints*.

The deformation of a TD network is determined by the type of polyhedral structural units and by the vertex-connectivity (C) that specifies the number of polyhedral units sharing a vertex. The vertex-connectivity is related to (see Eq. 1) but is different from the average coordination number r .

3.1 Rigidity of Polyhedral Structural Units

An isolated single regular polyhedral unit can be specified by two parameters: the dimension (δ) of the unit and its number of vertices (V). The dimension of the unit is the minimum dimension necessary to embed it. For example, $\delta = 1$ for a rod, 2 for a triangular unit, and 3 for a tetrahedron. It is clear that $\delta \leq d$ (the dimension of the network) and that $V \geq (\delta + 1)$.

When a regular polyhedral structural unit is rigid, the total number, N_u , of independent constraints in the unit satisfies the following relation:

$$N_u = \delta V - \left[\frac{\delta(\delta + 1)}{2} \right]. \quad (3)$$

Table 1 Degrees of freedom (f) of d -dimensional TD networks of rigid units (δ, V) with C units sharing a vertex (with the assumption $h = \theta = 0$) based on Eqs. (4) and (5).

Structural unit	δ	V	n_u	d	C	f

Octahedron	3	6	2	3	2	-1
Cube	3	8	2.25	3	2	-1.5

Therefore, the number of independent constraints per vertex ($n_u = N_u/V$) in a rigid unit is

$$n_u = \delta - \left[\frac{\delta(\delta + 1)}{2V} \right]. \quad (4)$$

A major advantage of PCT is that Eq. (3) counts correctly the number of independent constraints in a rigid unit. From Eq. (4) and the values of n_u listed in Table 1 for several simple polyhedral units, one sees that n_u increases with both V (for fixed δ) and δ (for fixed $V > \delta$). When a structural unit is non-regular and rigid, other parameters, in addition to δ and V , are needed to specify the structural unit.

3.2 Existence of Topologically Disordered ($d = 3$) Networks

For an extended three-dimensional network (made up of a single type of structural unit) with an average C structural units sharing a vertex, the degrees of freedom, f , per vertex are

$$f = 3 - C \quad n_u = 3 - C \left[\delta - \left\{ \frac{\delta(\delta + 1)}{2V} \right\} \right]. \quad (5)$$

If f is positive, a network can exist. When f is negative, a TD network cannot exist. Thus, $f = 0$ provides a boundary for the existence of TD networks.

If additional constraints (θ) are present at the shared corners (for example, bond angle constraints) or if there are internal degrees of freedom (h) within the structural units (for example, there is one internal degree of freedom in a unit made up of a pair of edge shared tetrahedra), then Eq. (5) can be modified as follows:

$$f = (3 - \theta) - C \left[\delta - \left\{ \frac{\delta(\delta + 1)}{2V} \right\} - \left(\frac{h}{V} \right) \right]. \quad (6)$$

The degrees of freedom of TD networks are also listed in Table 1 for several rigid structural units for different values of connectivity. It should be noted that SiO_2 with $V = 4$, $C = 2$, $\delta = d = 3$ satisfies the condition of isostaticity ($f = 0$). Similarly, a two-dimensional TD network of corner-sharing rigid triangles (a candidate structure of B_2O_3 glass) is also isostatic.

3.3 Glass-forming Ability

According to PCT, a glass can be formed if and only if it can exist as a TD network (i.e. only if $f \geq 0$). With increasingly positive values of f , however, the existing TD network becomes progressively more floppy and may crystallize beyond a certain value $f(q)$ that depends on the cooling rate, q . Thus, glass formation is possible in the range for which $0 \leq f \leq f(q)$. With positive and increasing f , the potential energy of interaction (the chemical energy) increases because of unsatisfied chemical bonds. With decreasing and negative f , the strain energy in the system increases. In other words, an isostatic network represents a minimum in the total energy of the system. For this reason, the glass-forming ability is best under isostatic condition ($f = 0$) and becomes poor as f increases. The $f = 0$ boundary is termed the *isostatic boundary* of glass formation and the $f(q)$ boundary the *kinetic boundary* of glass formation.

3.3.1 Glass-forming Ability and the Condition of Isostaticity ($f = 0$)

The isostaticity condition is satisfied in three dimensions for tetrahedral structural units ($V = 4$) with two units sharing every vertex ($C = 2$) as is the case for SiO_2 , GeO_2 , and BeF_2 , which are known as excellent glass formers. The isostatic condition is also satisfied for two-dimensional networks made of corner-sharing triangles. This is often considered to be the reason why B_2O_3 is a strong glass former.

An interesting application of the isostatic boundary concept is identification of limiting isostatic composition for glass formation. Consider the example of nitridation of alkali-silicate glasses. In silicon oxynitride glasses, nitrogen substitutes for oxygen forming two kinds of vertices: oxygen vertices with $C = 2$ and nitrogen vertices with $C = 3$. Adding nitrogen to silica (for which f is 0) makes f negative. This suggests that nitridation of silica will be difficult. However, addition of alkali creates non-bridging oxygens (with $C = 1$). Thus, nitrogen can be added to alkali-silicates while keeping f non-negative. In fact one can calculate the maximum amount of nitrogen that can be incorporated into an alkali-silicate glass as

a function of the alkali content. Consider glass formation in an alkali silicon oxynitride system of the general composition $x \text{Na}_2\text{O} \cdot (1 - x)[\text{SiO}_{(2-y)} \text{N}_{(2y/3)}]$. Note that $0 \leq y \leq 2$ and $0 \leq x \leq 1$. This system has three types of vertices: non-bridging oxygens with $C = 1$, bridging oxygens with $C = 2$, and bridging nitrogens with $C = 3$. The isostatic condition gives the limiting solubility of nitrogen, $y_{\max} = 3x/(1 - x)$. For $y > y_{\max}$, f becomes negative. Whereas systematic investigations of nitridation of alkali-silicate glasses are not available, it is known that nitridation becomes easier upon increasing the alkali content [16].

Another example is provided by binary alkali-tellurite systems. Pure TeO_2 with trigonal bipyramid structural units is over-constrained and does not form glass. Glass formation improves upon addition of alkali oxide because of formation of non-bridging oxygens, thereby increasing f and thus making it possible to form glasses when sufficient alkali oxide is added. Narayanan and Zwanziger [17] have rationalized in this way glass formation in alkali-tellurite systems.

3.3.2 Glass Formation Under Hypostatic ($f > 0$) Conditions

This condition is best exemplified by the $x \text{Na}_2\text{O} \cdot (1 - x) \text{SiO}_2$ system where addition of Na_2O leads to conversion of bridging oxygens (with $C = 2$) into non-bridging oxygens (with $C = 1$). The average value of degrees of freedom increases with increase in x :

$$f(x) = \frac{3x}{2 - x}. \quad (7)$$

It is well known that glass formation in alkali-silicate systems becomes difficult for large value of x , especially when $x > 0.5$.

3.3.3 Glass Formation Under Hyperstatic ($f < 0$) Conditions

When $f < 0$, a TD network cannot exist. The excess strain energy can, however, be accommodated in a variety of ways that increase the value of f toward $f = 0$. One possibility is that the network crystallizes, thereby reducing the number of independent constraints by converting some into dependent ones. A second possibility is that new structural units form by breaking weaker constraints. When constraints are broken within structural units, the polyhedra become distorted. The existence of an extended TD network of distorted AB_V polyhedral units (where the BAB angular constraint is broken at the A site but the AB length constraint remains intact) is demonstrated by the example of glass formation in the $\text{CaO-Al}_2\text{O}_3$ binary system. Since neither component is a network former, glass formation in this binary system is poor. If the presence of CaO stabilizes four-coordinated

aluminum ions, Al^{IV} , with two AlO_4 tetrahedra sharing an oxygen vertex (as in silica), then the composition having 50% CaO should be a good glass former. However, experimental results show that glasses in this system form only in a small composition range at about 65% CaO [18]. It is possible to rationalize this observation with the constraint theory. Recently, Jahn and Madden [19] have reported from MD simulations that at 2350 K aluminum is present in Al_2O_3 melt in several different coordination states; about 54% Al^{IV} , 41% Al^{V} , 4% Al^{VI} , and 1% Al^{III} . Further, it was observed that some of the oxygens are present as O^{III} , oxygen coordinated by three aluminums (also known as oxygen triclusters), and the remaining as normal bridging oxygens, O^{II} . One can use this structural information and PCT to rationalize why the 65% CaO composition forms best glasses in this system. First, it can be assumed that the structures of Ca -aluminate and alumina melts are similar except for the incorporation into the network of O from CaO . Next, one can simplify the structural information by neglecting the concentrations of Al^{VI} and Al^{III} . Let z be the fraction of Al^{IV} and $(1 - z)$ that of Al^{V} . Then, for the composition $x \text{CaO} \cdot (1 - x) \text{Al}_2\text{O}_3$, one shows with PCT that the degrees of freedom, f , is given by

$$f(x, z) = \frac{12x + 6z - 6xz - 9}{3 - 2x}. \quad (8)$$

When $f = 0$, Eq. (8) gives the following expression for the isostatic composition x^* [$x(f = 0)$] in terms of z :

$$x^*(z) = \frac{3 - 2z}{4 - 2z}. \quad (9)$$

For $z = 0.54$, Eq. (9) gives $x^* = 0.65$, the same value as for the best glass-forming composition [18].

3.4 Existence of Super-Structural Units

In B_2O_3 glass the presence of rigid, planar boroxol B_3O_6 units made up of three trigonal BO_3 units is well established [20]. In contrast to basic polyhedral units, AB_V , where a single A atom is coordinated by B atoms, *super-structural* units such as boroxol units contain more than one A atom. Do super-structural units then exist in other borate glasses? It is a question that has long persisted in the oxide-glass science.

Super-structural units may be energetically more favorable in systems with long-range interactions. However, their larger size raises difficulties to match the density of networks with the observed density of glass. For example, the boroxol units are topologically equivalent to the basic BO_3 trigonal unit (both have $\delta = 2$ and $V = 3$). If all BO_3 trigonal units in B_2O_3 glass are replaced by B_3O_6 boroxol units, the length scale of the structural unit is doubled (the volume thus increasing by a factor of 8)

while the mass of the unit is only tripled so that the density of a network of boroxol units is only 3/8 of that of a network of trigonal units. Further, based on topological considerations mentioned before, an extended 3-D network can incorporate only a small fraction of super-structural units with $V > 4$. For this reason, the dipentaborate and the di-triborate groups, two of the six super-structural units listed by Wright [20], probably do not exist in significant concentrations.

4 The Bond Constraint Theory

As originally formulated by Phillips [1] for covalent networks, structural units are not considered in BCT. Instead, the system is viewed as a network of atoms at the vertices and covalent linear bonds at the edges. These covalent linear bonds provide $r_i/2$ linear constraints at the i th vertex of coordination number r_i . In addition, there also exist $[r_i(d - 1) - d(d - 1)/2]$ covalent angular-bond constraints at the i th vertex for a d -dimensional network. The average number of constraints, n , per vertex is, therefore,

$$n = \left(\frac{r}{2}\right) + [r(d - 1) - \{d(d - 1)/2\}], \quad (10)$$

where r is the average vertex coordination number. The condition of isostaticity ($n = d$) gives the following value for the critical coordination number r^* (also called the rigidity percolation threshold):

$$r^* = d(d + 1)/(2d - 1). \quad (11)$$

Note that $r^* = 2$ for $d = 2$ and $r^* = 2.4$ for $d = 3$. It must be emphasized that Eqs. (10) and (11) assume that the angular constraints are intact at *every* vertex. This assumption does not always hold true as illustrated by silica where the angular constraints at oxygens are broken, which is generally the case for elements that do not belong to groups III, IV, and V and do not exhibit $\text{sp}^{(n)}$ hybridization.

Application of BCT to non-covalent systems with long-range interactions such as ionic systems is approximate at best, and questionable most of the time, because these systems do not lend themselves to the count of simple nearest-neighbor constraint. For ionic systems, it is thus preferable to use PCT with structural units defined by the radius ratio of cations to anions.

4.1 Self-organization and the Intermediate Phase

Self-organization designates chemical and/or topological rearrangements in a network that take place

spontaneously to reduce the overall energy in the system [21]. An important consequence of this process is that it allows a system to exist as an isostatic network over a range of coordination numbers or compositions. This range is sometimes known as the intermediate phase or reversibility window [22]. The range depends on the system considered and, to some extent, on its thermal history as well as on the property being measured (e.g. enthalpy release during relaxation, Raman frequency shifts in glasses, or activation energy of viscosity). For example, a coordination number range from 2.39 to about 2.52 has been reported for the intermediate phase in $\text{Ge}_x\text{Se}_{(1-x)}$ system from Raman frequency shifts [22], and a range from $r = 2.35$ to about 2.45 in the $(\text{Na}_2\text{O})_x(\text{SiO}_2)_{(1-x)}$ system from enthalpy relaxation [23]. Interestingly, Wang et al. [24] found no evidence of any intermediate phase in the Ge–As–Se system. Also, Shatnawi et al. [25] found no discontinuities or breaks but only smooth variation with respect to composition in the structural response of $\text{Ge}_x\text{Se}_{(1-x)}$ glasses in the range $0.15 < x < 0.40$ implying the absence of any phase transition associated with the start and end of the intermediate phase range.

4.2 Non-bridging Vertices (or Singly Coordinated Atoms)

There has been much discussion in the literature [26] about the role of dangling vertices (or non-bridging nodes) and their influence (if any) on the rigidity characteristics of a network. At least conceptually, it is clear that dangling vertices should not affect the stiffness of the network because they are not network-forming. In this respect, a confusion in the literature exists primarily because of the way constraints and degrees of freedom are counted. Clearly, if a dangling vertex is counted as being part of the network, then it is necessary to count also the length and angle constraints associated with it. A dangling vertex adds three degrees of freedom but also three constraints (one length and two angles), so that it does not make any net contribution to the degrees of freedom in a network if the counting is done correctly. However, the problem is that extra degrees of freedom often appear when the angular constraints of the dangling vertices are not included in the count [26, 27]. Because these extra degrees of freedom are associated with the floppiness of the dangling vertices themselves, they do not influence the rigidity or the flexibility of the underlying network. Thus, the opinion of this writer is that it is best to disregard the onefold coordinated atoms (i.e. dangling or non-bridging vertices) as they have no influence on the rigidity characteristics of a network.

4.3 Glass-forming Ability in Chalcogenide Systems

4.3.1 Ge–Se System

For the binary $\text{Ge}_x\text{Se}_{(1-x)}$ system, the average coordination number $r(x)$ is $(2 + 2x)$ since $r(\text{Ge}) = 4$ and $r(\text{Se}) = 2$, and the system is isostatic at $x^* = 0.2$ (corresponding to the $\text{Ge}_{1/5}\text{Se}_{4/5}$ composition). According to Tichy and Ticha [28], however, the best glass-forming compositions lie on the Se-rich side in the range $0.06 < x < 0.15$. To rationalize this apparent discrepancy, Tichy and Ticha [28] suggested to view the $\text{Ge}_x\text{Se}_{(1-x)}$ system as an extended chemically ordered network of short, linearly-rigid $(\text{Se})_k$ chains containing k seleniums that are cross-linked by Ge atoms. The ends of the Se chains are connected to Ge atoms so that four such chains share a Ge atom. Note that since $x = 1/(1 + 2k)$, k is 2 at $x = 0.2$. A network with $k > 2$ (corresponding to $x < 0.2$) should be floppy ($f > 0$). However, one can show that some of the degrees of freedom (let us denote these by $f^\#$) in such a network for $x < 0.2$ are associated with the dihedral rotation of the inner seleniums ($\text{Se}^\#$), those inside the selenium chains ($-\text{Se}-\text{Se}^\#-\text{Se}-$). A $\text{Se}^\#$ atom can rotate dihedrally about the line joining its two neighboring Se without influencing the deformation pattern of the network (Figure 2). This is one example where certain internal degrees of freedom decouple from the rigidity of the overall network. In another example the extra degrees of freedom associated with a singly coordinated atom (i.e. a dangling vertex) decouple from the rigidity of the overall network. Clearly such decoupled degrees of freedom can be disregarded as far as network rigidity is concerned. The network, therefore, can satisfy the isostaticity condition in the range $x < 0.2$ by forming chemically ordered networks with an appropriate value of the k for the Se-chains. A value of $k = 3$ corresponding to $x = 1/7$ (or about 0.14) is close to the composition where best glass

Figure 2 Schematic of a Se-chain with five seleniums connecting two Ge atoms in an isostatic network (not shown). The inner $\text{Se}^\#$ can rotate dihedrally about the dashed line connecting its neighboring seleniums without influencing the rigidity of the network. This dihedral motion of inner seleniums is an internal degree of freedom decoupled from the rigidity of the overall network.

formation is observed, explaining why good glass formation takes place for $x < 0.15$.

For $x > 0.2$, there is experimental evidence for edge-shared GeSe_4 tetrahedra [29]. Because the presence of edge sharing does not change the value of r , the BCT results are not affected but edge sharing does cause differences in the intermediate-range topology. When one considers a pair of edge-shared tetrahedra as a single unit with four Se vertices (and two internal Ge atoms), such a bi-tetrahedral unit has an internal degree of freedom, namely rotation about the shared edge. This additional flexibility allows isostaticity to hold beyond the GeSe_2 composition ($x = 1/3$) in the PCT formalism even though the BCT results do not change. It is also clear that the presence of Ge–Ge homopolar bonds [16] – that must exist for $x > 0.33$ – does not influence the short-range topology of the network. Hence, the BCT consequences do not change.

4.3.2 As–Se System

Since $r(\text{As}) = 3$ in the $\text{As}_x\text{Se}_{(1-x)}$ system, $r^* = 2.4$ corresponding to $x^* = 0.4$. But good glass formation has been observed in the Se-rich range from $x \sim 0$ to $x \sim 0.23$. As in the Ge–Se system, this discrepancy can be rationalized by viewing the As–Se glasses for $x < 0.4$ as a chemically ordered network made up of linearly-rigid (Se_k) short chains, three of which being connected to every As atom. If one eliminates the internal degrees of freedom associated with the dihedral rotations of $\text{Se}^\#$ in the Se chains, it follows that these chemically ordered $\text{As}((\text{Se})_k)_{3/2}$ systems are isostatic for $x \leq 0.4$. Note that since $x = 2/(2 + 3k)$, $k \geq 2$ corresponds to $x \leq 0.25$, which fits well the reported composition range for good glass formation [28].

4.4 Composition Variation of Properties in Glass-forming Systems

Most properties of glasses exhibit rather uninteresting monotonic continuous variations even when r crosses its isostatic value. Only some configurational properties show extremum values with respect to r at the rigidity percolation threshold (i.e. at $r^* = 2.4$). Tatsumisago et al. [30] reported that the configurational heat capacity and the activation energy of viscosity exhibited minima in the Ge–As–Se system at $r = 2.4$. Similar results were obtained by Senapati and Varshneya [31] in the Ge–Se and Ge–Sb–Se systems. It is worth noting that by investigating a range of Ge–As–Se compositions, all having the same values of r , Wang et al. [24] have reported that values of the configurational properties are not a unique function of r implying that topology alone is not sufficient to determine the variation of properties with composition, effect of chemical disorder must also be considered.

5 Temperature-Dependent Constraints

5.1 The Influence of Thermal Energy

Implicit in the original PCT and BCT theories was the notion that constraints are fixed for good – either intact ($= 1$) or broken ($= 0$) – and that they do not vary with temperature (T). Thermal energy was implicitly neglected in the original theories which were thus valid only at $T = 0$ K. To remedy this problem, Gupta [5] introduced the concept of a T -dependent bond constraint. He argued that, if E_i is the energy of a certain class of bonds, then the value of the corresponding constraint $h_i(T)$ should be expressed by a Boltzmann expression:

$$h_i(T) = 1 - \exp\left(-\frac{E_i}{k_B T}\right), \quad (12)$$

where k_B is the Boltzmann constant. Note that the value of h_i always lies in the interval $[0,1]$, being zero in the high-temperature limit, equal to 1 at sufficiently low temperatures, and decreasing monotonically with increasing T . Physically, a fractional value of a bond constraint means that only a fraction of i th type of bonds are intact at a given instant. One may associate a characteristic temperature T_i for the i th type of constraint as follows:

$$T_i = \frac{E_i}{k_B \ln 2}, \quad (13)$$

so that this constraint can be considered effectively as broken ($= 0$) for $T > T_i$ and intact ($= 1$) for $T < T_i$. For both stretching and bending constraints, this formalism has been validated by comparisons of the standard deviations of the partial distributions calculated for glassy and crystalline alkali disilicates as a function of temperature in MD simulations [9].

The average degree of freedom per vertex, $f(T)$, in the network thus becomes T -dependent and (for $d = 3$) is given by

$$f(x, T) = d - \sum_i n_i(x) h_i(T). \quad (14)$$

Since h_i is a decreasing function of T , $f(T)$ always increases with temperature.

5.2 Extension of the Topological Constraint Theory to Supercooled Liquids

In 1999, Gupta [6] extended the notion of T -dependent bond constraints to glass-forming supercooled liquids: “*Since the structure of a glass formed by cooling a liquid is the same as the structure of the liquid at the glass transition (or fictive) temperature, T_g it follows that if the glass structure is an extended TD network, then such a network*

must also exist in the super-cooled liquid state at T_g ." More importantly, he argued that the configurational entropy, $\Delta S(T)$, of a supercooled liquid is approximately proportional to the average degrees of freedom per vertex, $f(T)$. This result, later substantiated by Naumis [32], leads to several important consequences:

- a) At the Kauzmann temperature, T_K , defined by $\Delta S(T_K) = 0$, the degrees of freedom vanish:

$$f(T_K) = 0. \quad (15)$$

- b) From the Adam–Gibbs theory of viscosity, it follows that the temperature-dependence of viscosity is simply related to that of $f(T)$:

$$\ln \eta(T) = \ln \eta(\infty) + \frac{A}{T f(T)}. \quad (16)$$

Here, A is a constant independent of T .

- c) The fragility, m , of a liquid defined as

$$m \equiv \frac{1}{T_g} \left[\frac{\partial \log_{10} \eta}{\partial (1/T)} \right]_{T=T_g}, \quad (17)$$

is related to the temperature-dependence of f as follows:

$$m \equiv \left[\log_{10} \frac{\eta_g}{\eta_\infty} \right] \left[1 + \frac{\partial \ln f}{\partial \ln T} \right]_{T=T_g}. \quad (18)$$

The value of $\log [\eta_g/\eta_\infty]$ is about 16. The variation of the degrees of freedom, $f(T)$, with T , for good, poor, and non-glass-forming liquids is shown schematically in Figure 3. From Eq. (16), one then concludes that the cause of the non-Arrhenian nature of the viscosity is the temperature-dependence of bond constraints.

Figure 3 Schematic variation of degrees of freedom (f) in three supercooled liquids with increasing temperature normalized with respect to the Kauzmann temperature (T_K). Curve (a) represents a strong glass former, curve (b) a fragile glass former, and curve (c) a non-glass former for which a TD network cannot exist (Source: From [6]).

5.3 Temperature – Scaling of Viscosity (η) and the MYEGA Equation

Substituting Eqs. (12) and (14) in Eq. 16 and assuming that only one type of constraints (with n constraints per vertex) varies within the temperature range of interest, one obtains the following temperature scaling of viscosity for supercooled liquids:

$$\ln \eta(T) = \ln \eta(\infty) + \frac{A}{T[(3-n) + n \exp(-E/k_B T)]}. \quad (19)$$

For deeply supercooled liquids in the vicinity of the glass transition, n is approximately equal to 3 and Eq. (16) simplifies to

$$\ln \eta(T) = \ln \eta(\infty) + \frac{B}{T} \exp\left(\frac{E}{k_B T}\right), \quad (20)$$

where B is a new constant. This Eq. (20) is the well-known MauroYue-Ellison-Gupta-Allan (MYEGA) expression [33] for the T -dependence of the equilibrium viscosity, which has been remarkably successful in fitting the experimental data on the T -dependence of viscosity for a large number of inorganic and organic liquids. It should be noted that, like the Vogel-Tammann-Fulcher (VFT) equation, the MYEGA has only three fitting parameters but, unlike VFT, it does not exhibit any divergence of viscosity at any finite temperature.

5.4 The Composition Variation of the Glass Transition Temperature, T_g

If the value of the parameter A in Eq. (16) has a negligible composition dependence, then it follows from this equation that

$$T_g(x)f[T_g(x)] = T_g(x_{\text{ref}})f[T_g(x_{\text{ref}})] = \text{const.} \quad (21)$$

Here, x_{ref} is a reference composition. The importance of Eq. (21) cannot be overstated. It provides a means of modeling the composition dependence of T_g from the knowledge of the atomic level short-range order as a function of composition. Traditionally, such information on the short-range order has been obtained from X-ray or Neutron diffraction studies. Nowadays, such information can also be obtained accurately using MD studies.

Gupta and Mauro [7] used the T -dependent constraint theory to rationalize quantitatively the variation of the glass transition temperature, $T_g(x)$, with composition in the binary $\text{Ge}_x\text{Se}_{(1-x)}$ chalcogenide system. Their analysis resulted in the modified Gibbs–DiMarzio equation:

$$T_g\left(0 \leq x \leq \frac{1}{3}\right) = T_g(0) \left[\frac{1}{1 - (ax)} \right], \quad (22)$$

with a value of the parameter $\alpha = 5/3$, which is the value observed experimentally [31]. In addition, using Eq. (18), Gupta and Mauro [7] were also able to explain the variation of the fragility, m , as a function of composition.

Mauro et al. [8] later applied the T -dependent constraint theory to binary alkali-borate systems where a wealth of structural information is available as a result of years of X-ray diffraction and NMR spectroscopy

Figure 4 Composition dependence of the glass transition temperature for the (a) sodium borate and (b) lithium borate systems. Solid curves: predicted $T_g(x)$ using the temperature-dependent TCT. Points: experimental data (Source: From [8]).

experiments. The agreement for both T_g and m between TCT and experimental results is remarkable considering that only one fitting parameter was used for all the data (see Figures 4 and 5). Using a similar approach, Smedskjaer et al. [34] have successfully extended the T -constraint theory to ternary system $\text{Na}_2\text{O}-\text{CaO}-\text{B}_2\text{O}_3$ system. In 2011, they also analyzed the four component $\text{Na}_2\text{O}-\text{CaO}-\text{B}_2\text{O}_3-\text{SiO}_2$ system [10].

Figure 5 Variation of fragility with composition in the (a) sodium borate and (b) lithium borate systems. Curves calculated with the T -dependent TCT. The step increase in fragility around $x = 0.2$ is a consequence of a fragility transition in these systems (Source: From [8]).

5.5 Fragility (or Rigidity) Transitions and Iso- T_g Regimes

A generalized T -dependent activation energy, $H(T)$, is defined as the slope of the Arrhenius plot of viscosity:

$$H(T, x) = k_B \frac{\partial \ln \eta}{\partial (1/T)}. \quad (23)$$

The ratio, $H(T_g, x)/(k_B T_g)$, is proportional to the fragility m . In some systems, the activation energy (or fragility) shows rounded discontinuities as a function of T or as a function of composition, X . These jumps are referred to as fragility transitions. An example of such transition in the alkali-borate systems is shown in Figure 5. Fragility transition as a function of temperature for a fixed composition is illustrated in Figure 6. In a temperature-induced fragility transition, a system always becomes more fragile at higher temperatures simply because more constraints are broken as the temperature is increased.

Mauro et al. [8] made an interesting observation in the binary alkali-borate melt $x\text{M}_2\text{O} \cdot (1-x)\text{B}_2\text{O}_3$ systems where T_g appears to be a constant function of composition for a small composition range. They called this composition range the “iso- T_g regime” (Figure 4). The iso- T_g step results when a bond constraint breaks exactly at T_g . It can be shown that, within the iso- T_g regime, the fragility remains constant and equal to the low value of about 16 that is observed for strong glasses. Interestingly, the composition range of the iso- T_g regime (at least in the alkali-borate system) is nearly the same as that of the reversibility window observed by Boolchand and colleagues [22]. This coincidence raises the possibility of some connection between the two phenomena, an area that requires further investigation.

Figure 6 Contrast between strong (SiO_2) and highly fragile (O-Terphenyl, OTP) in plots of viscosity against reciprocal temperature, and intermediate cases of liquids fragile at high temperatures and becoming strong at low temperatures (water, glass-forming metals) through a diffuse transition (cf. Chapter 3.8; Source: From [35]).

6 Topological Constraint Theory, Thermodynamics, and the Potential Energy Landscape Formalism

The impressive applications of TCT demand answers to fundamental questions such as how is TCT connected to the thermodynamics of liquids and glasses and how to formulate TCT from the first-principles statistical physics of potential-energy landscapes of liquids and glasses. This is an area that has not received much attention so far except for the work of Naumis and coworkers [13, 32] that we summarize in this section.

Naumis uses simple harmonic potentials to express the Hamiltonian (H) of a floppy system as follows:

$$H = \sum_1^{3N} \frac{p_j^2}{2m} + \sum_1^{3N(1-x_f)} \frac{1}{2} m \omega_j^2 q_j^2 + \sum_1^{3Nx_f} \frac{1}{2} m \omega_o^2 q_j^2. \quad (24)$$

Here, x_f is the fraction of floppy modes ($= f/3$); p_j and q_j are, respectively, the momentum and position coordinates of oscillators representing vibrational modes of frequency ω_j and floppy modes of frequency ω_o . For real systems, one has to use more sophisticated interaction potentials. Nonetheless, a harmonic model gives a reasonable qualitative feel of the thermodynamics of the floppy modes. Naumis assigns a small but finite frequency ω_o ($< \omega_{\text{vib}}$) to each floppy mode. The equilibrium thermodynamics of this Hamiltonian can be calculated easily. The result for the internal energy U of the system is

$$U(T) = (3-f)NkT D\left(\frac{\hbar\omega_D}{kT}\right) + fN \left[\frac{\hbar\omega_o}{\exp\left(\frac{\hbar\omega_o}{kT}\right) - 1} \right]. \quad (25)$$

Here, D is the well-known Debye function and ω_D is the Debye frequency. According to Naumis, the expression for entropy is as follows:

$$S(T) = k \ln \left[\left(\frac{12\pi kT}{h} \right)^{N(3-f)} \prod_1^{N(3-f)} \left(\frac{1}{\omega_j} \right) \right] + Nf k \ln \left(\frac{12\pi kT}{h\omega_o} \right). \quad (26)$$

The last terms in Eqs. (25) and (26) represent the contributions of the floppy modes and constitute the configurational energy and entropy, respectively. As discussed in Section 5.2, the configurational entropy is proportional to f .

From Eq. (25), the configurational heat capacity, ΔC_V , is given by

$$\Delta C_V = fNk \frac{x^2 e^x}{[e^x - 1]^2} + NkT \left[\frac{x}{e^x - 1} \right] \left(\frac{\partial f}{\partial T} \right), \quad (27)$$

where $x = h\omega_o/kT$.

As Naumis has pointed out, the physical picture in the PEL is clear. Since ω_o is small, the curvatures of the potential energy surface at the inherent structures are small in the floppy directions. Naumis refers to these directions as channels in the landscape. The landscape is flatter in these channels, thus allowing greater configurational entropy and greater structural freedom upon increase in T and thus greater fragility.

7 Perspectives

Over the last 25 years, TCT has evolved from theoretical inquiries about the existence of Zachariasen's TD networks and easy glass formation in simple systems to a widely used scheme for modeling variations of properties with composition in multicomponent glasses and glass-forming liquids. The trends predicted by TCT are in good agreement with experimental results. This is largely because TCT takes as input the observed or modeled variation of topology with composition and a fundamentally sound temperature-dependence of chemical bond strengths. In this sense, TCT represents a major leap in the development of science-based engineering of new glass compositions.

In spite of its success, several limitations and fundamental issues remain unresolved. We list some of these here.

- 1) For systems with short-range interactions where BCT is applicable, it is unclear when to treat the angular constraints as broken (even at low temperatures). For example, why is the angular constraint broken at oxygens in silica? Are they broken at Se in selenides? It appears that angular constraints are intact primarily in group III, IV, and V elements that exhibit $sp^{(n)}$ hybridization. Clearly, a more detailed understanding of the basis of the angular constraints will lead to more accurate predictions of BCT.
- 2) Extension of TCT to systems with long-range potentials (especially ionic interactions) remains vague and questionable at present. Whereas BCT applies only to systems with short-range covalent interactions, PCT works better for ionic systems. The effects of chemical order in BCT and of chemical disorder in PCT need further examination. There is a clear need for a more fundamental basis for applying TCT to chemically disordered systems having long-range interactions.
- 3) It has been noted that the rigidity percolation threshold may not occur at a single composition, but over a range of compositions because of either localization of constraints or localization of degrees of freedom in an

otherwise isostatic matrix. Whereas a discussion of iso- T_g range is presented, there does not exist at present a theory to determine the rigidity percolation composition range.

- 4) The role of intermediate-range topology (ring-size distribution) in determining the deformation of a network remains unclear. For example, edge-sharing between tetrahedra in the Ge-Se system appears to have no effect on the BCT results since both edge and corner sharing give rise to identical short-range topology (i.e. the same value of r).
- 5) Whereas an approximate relation between configurational entropy and degrees of freedom has been discussed, a more rigorous understanding of constraints (or degrees of freedom) in general in terms of features of the PEL is needed to embed the TCT in the general statistical physics of the disordered condensed state.
- 6) The minimum free-energy configuration in the supercooled liquid state corresponds to the most probable network configuration. Thus, a relationship between the free energy of the supercooled liquid and the nature of constraints is expected. Establishment of such a relationship will provide a sound thermodynamic foundation of TCT and will provide answers to the important questions as to why good glass-forming compositions are also low-temperature eutectics.
- 7) All systems have configurational fluctuations at a finite temperature. The present formulation of TCT applies only to the average network configuration so that the influence of fluctuations is not accounted for. Clearly, extension of TCT to include configurational fluctuations is desirable to model fluctuation-based properties.

In spite of these limitations, it is important to emphasize that the success of TCT in some systems has been remarkable. But with increasing need to apply TCT to a large variety of systems, it is necessary to develop a theoretically sound basis to resolve these issues.

Atomistic Simulations of Glass Structure and Properties

Akira Takada

Research Center, Asahi Glass Co. Ltd., Hazawa-cho, Yokohama, Japan

1 Introduction

Following Zachariasen's epoch-making *continuous random network* (CRN) model [1], the first generation of atomistic models of glass relied on craft construction of ball-and-stick representations of atomic structures. Perhaps the most successful model was constructed for SiO_2 glass by Bell and Dean [2] who patiently assembled manually rods and balls to compose 188 tetracoordinated units with a total of 614 atoms. The disordered linkage of the SiO_4 groups, which were assumed to be rigid, did satisfy Zachariasen's structural rules.

From the angles and distances they measured, Bell and Dean also determined the pair distribution functions (PDF) for Si–Si, Si–O, and O–O, from which they derived a radial distribution function (RDF) that was in good agreement with the experimental data over their full range of definition, i.e. out to a distance of about five times the Si–O bond length. Yielding in particular an average O–Si–O bridging angle of 153° , this model enabled the three-dimensional atomic configuration of SiO_2 glass to be visualized, but it suffered from an obviously large arbitrariness in its handmade combination of building blocks. In addition, the model did not lend itself to estimations of physical properties. An exception was the density, which was calculated for an internal portion of the model system consisting of 72 SiO_2 units, to yield a value of 1.99 g/cm^3 that proved to be much lower than the actual 2.20 g/cm^3 .

Atomistic simulations have rendered such mechanical models obsolete as they readily provide not only atomic coordinates but also predict physical properties for glass

and melts of any composition under a variety of temperature, pressure, or energy conditions. Besides, the accuracy and versatility of these calculations have been improving steadily, thanks to faster computing processors, more efficient algorithms, and bigger systems investigated. Originally, these simulations were mainly developed to give exact solutions to problems in statistical mechanics which would otherwise have been intractable for complex states of matter such as liquids, glasses, or aggregates.

The first simulations were made with the Monte-Carlo (MC) method (e.g. [3]), which had been devised in the 1930s to solve general mathematical and statistical problems. It took advantage of the first electronic computers to sample the configurations of the system according to Boltzmann statistics, and weight them evenly when calculating the associated properties of interest. Because of this reliance on Boltzmann statistics, however, only equilibrium states can be investigated in MC simulations. At the cost of much computational complexity, the advantage of molecular dynamics (MD) simulations (e.g. [4]) is to characterize at every moment the state of the system by the positions and momenta of its constituting atoms and, thus, to account for the dynamics of the system whether in equilibrium or not. For SiO_2 , the first MD simulation performed by Woodcock et al. [5], for instance, dealt with the anomalous properties of the melt and assigned increases in diffusion coefficients to pressure-induced structural changes. Following this pioneering study on a real material, a great many MD simulations have been carried out on glass/melt systems since that time.

Interatomic potentials are critical ingredients in both MC and MD simulations (e.g. [4]). As a preamble, it is thus appropriate to begin this chapter with a brief review of the manner in which they are determined within the general framework of numerical simulations. The principles of MC and MD simulations will then be

Reviewers: J. Du, Materials Science and Engineering, University of North Texas, Denton, TX, USA

J. Habasaki, Innovative and Engineered Materials, Tokyo Institute of Technology, Yokohama, Kanagawa, Japan

presented. Finally, simulations made on amorphous oxide glasses will illustrate the interest and diversity of results that can be obtained with MD simulations and their complementarity with those of experimental studies. Amorphous SiO_2 , silicates, or phosphates will be mentioned but special interest will be paid to the structure of B_2O_3 glass that actually represents stringent tests of simulations as it requires accurate descriptions of both short- and medium-range order to be understood. Other important applications of atomistic simulation to transport properties are discussed in Chapter 4.6.

2 Basics of Numerical Simulations

2.1 General Features

Atomistic simulations rely on statistical mechanical models. As such they may be performed within three main kinds of statistical ensembles. The canonical NPT ensemble (constant number of atoms, pressure, and temperature) is chiefly used in heating or quenching cycles. In contrast, the micro-canonical NVE ensemble (constant number of atoms, volume, and energy) is primarily used when properties are calculated within the precise framework of statistical mechanics. As for the grand canonical μVT ensemble (constant chemical potential, volume, and temperature), it is typically used to investigate chemical equilibrium in systems that can exchange energy and matter with a reservoir.

For an isolated macroscopic system made up of a very large number N of atoms, each having three degrees of freedom, the microscopic state at a given instant is completely specified by the values of $3N$ coordinates $r(i)$, collectively denoted by r^N , and $3N$ momenta $p(i)$, denoted similarly by p^N . The values of the variables r^N and p^N define a point in a $6N$ -dimensional space, called the phase space, symbolized by Γ_N . If $H(r^N, p^N)$ is the Hamiltonian of the system, the path followed by this point in the phase space is determined by Hamilton's equations:

$$\dot{r} = \frac{\partial H}{\partial p(i)} \quad (1)$$

$$\dot{p} = -\frac{\partial H}{\partial r(i)}, \quad (2)$$

where $i = 1, \dots, N$. In principle, $6N$ coupled equations subjected to $6N$ initial conditions should be solved to specify the values of all $r(i)$ and $p(i)$ at a given time.

The first difficulty encountered is that the timescale of microscopic processes is ultimately controlled by the 10^{-14} – 10^{-15} second period of atomic vibrations. In atomistic simulation, a time integration with similar discrete steps thus is required to describe accurately the time

evolution of a system. Even with today's most powerful computers, this constraint restricts simulations to low-viscosity conditions at which relaxation times (cf. Chapter 3.7) are lower than about 10^{-6} seconds to be consistent with the calculational time steps.

It follows that the glass transition cannot be investigated as a number of calculation steps of the order 10^{18} would be required to deal with a relaxation time of $\sim 10^3$ seconds. Likewise, crystal nucleation and growth or liquid–liquid phase separation take place too slowly to be subjected to atomistic simulations. Besides, simulated melts are quenched at cooling rates at least six orders of magnitude faster than the highest rates of $\sim 10^6$ K/s achievable practically. The fictive temperatures of the simulated glasses that then be up to 1000 K higher than those of real glasses, which one should keep in mind when making any kind of comparison between both kinds of materials.

Besides, a second difficulty stems from the fact that N is of the order of the Avogadro number (6.02×10^{23}) for any macroscopic system. Experience shows, however, that accurate results can be obtained for systems of only a few hundred or thousand atoms as long as structural units bigger than the system itself are not involved in the processes investigated. To avoid either creating surface or setting up a wall (Figure 1), periodic boundary conditions are usually imposed in numerical simulations. The cubic box is replicated throughout space to form an infinite lattice. As an atom moves in the original box, its periodic image in each of the neighboring boxes moves in exactly the same way. As an atom leaves the central box, one of its images will enter through the opposite face.

To simulate accurately a noncrystalline configuration in the cell, a larger number of atoms are nonetheless preferable. When a small cell of around several hundred atoms is studied, periodic boundary conditions, for

Figure 1 Schematic representation of periodic boundary conditions.

instance, prevent structural units larger than the cell from forming. As already alluded to, any structural unit or spatial fluctuation larger than the wavelength which is greater than half of the cell size cannot be calculated appropriately because the repeatedly arranged fragments would be involved in the results. On the other hand, the maximum number of atoms which can be currently processed is of the order of 10^5 – 10^6 . To check whether the number of atoms or the size of simulation cell is sufficient or not, the best way is to double the number of atoms and to maintain the same density through an adjustment of the cell size and then to make sure that there is little change in the calculated structural data.

2.2 The Importance of Interatomic Potentials

Strictly speaking, in numerical simulations the Hamiltonian should be calculated from the quantum wave-function equation, $H\psi = E\psi$, where ψ and E are the wave-function and energy of the system, respectively. As expounded in Chapter 2.9, such calculations require so much computing work that they are currently restricted to smaller systems typically made up of a few tens of atoms. In the present chapter, simulations made within a classical framework will thus be considered instead. They rely on the fact that the differences between vibrational and electronic energies and frequencies are so large that atomic vibrations may be considered to take place within a fixed electronic configuration. This is the celebrated Born–Oppenheimer approximation whereby the Hamiltonian of a system is expressed as the sum of kinetic and potential energies, which are functions of the selected set of coordinates $q(i)$ and momenta $p(i)$:

$$H(p, q) = K(p) + U_p(q). \quad (3)$$

In Eq. (3) the kinetic energy, $K(p)$, is simply expressed as a function of the mass and of the velocity calculated for each atom. The potential energy, $U_p(q)$, is much less readily determined because it strongly depends on the specific interactions between the various kinds of atoms present in the system. Quite generally, however, interaction potentials are markedly asymmetrical in terms of interatomic distances because they rise extremely steeply when atoms get mutually very close whereas they reach a constant value – the dissociation energy – when atoms become so distant that they can be considered as no longer bonded. As introduced in 1929 to represent isolated diatomic molecules, the Morse potential accounts well for this asymmetry:

$$U_p(r_{ij}) = E_0 \left[\left\{ 1 - \exp(-k(r_{ij} - r_0)) \right\}^2 - 1 \right], \quad (4)$$

where E_0 , k , and r_0 are the dissociation energy, a measure of the bond strength, and the equilibrium interatomic distance of the molecule, respectively, three parameters that are determined from vibrational spectroscopy data.

In a condensed phase, potentials are much more complicated since a given atom interacts with a great many others over distances that can be large. To keep the number of parameters as small as possible in the expression of potential energies, one thus groups into the same term all interactions between given pairs of like or unlike atoms regardless of their mutual distances. Although the Morse potential remains a good starting point for systems where bonding is covalent, other kinds of analytical expressions are generally used for potential energies in the MC and MD simulations dealt with in this chapter. As borne out by the variations with composition of macroscopic properties, atomic interactions have the simplifying feature that they are primarily pairwise in oxide or salt systems. This feature is embodied in the most popular potentials used for these systems, namely, the Buckingham,

$$U_p(r_{ij}) = A \exp\left(-\frac{r_{ij}}{\rho}\right) - \frac{C}{r_{ij}^6}, \quad (5)$$

and the Born–Mayer–Huggins potentials,

$$U_p(r_{ij}) = A \exp[B(r_{ij} - r_0)] - \frac{C}{r_{ij}^6} - \frac{D}{r_{ij}^8}, \quad (6)$$

where r_{ij} is the distance between two atoms, and A , B , r_0 , C , D are parameters inherent to each interaction (Figure 2).

In both potentials, the first, second, and third terms represent repulsive interaction, dipole–dipole dispersion, and dipole–quadrupole dispersion, respectively. In more precise formulations, ternary and higher-order effects must be accounted for so that the potential energy is made up of terms depending on the coordinates of individual atoms, pairs, triplets, etc.

Figure 2 Examples of potential energy models: Morse and Buckingham potentials used in B_2O_3 simulations for B–O and for O–O and B–B, respectively [6].

$$U_p = \sum_i u_1(r(i)) + \sum_i \sum_{j>i} u_2[r(i), r(j)] + \sum_i \sum_{j>i} \sum_{k>j} u_3[r(i), r(j), r(k)] + \dots \quad (7)$$

The first term u_1 is discarded in standard simulations because it accounts for external fields (i.e. wall, electrical field, gravity, magnetic field, and centrifugal force). The second term u_2 is the most important since it represents the relevant pair potentials. When determined empirically, it actually includes three-body and many-body effects, which is why models relying on simple pair potential model reproduce reasonably well liquid or glass structures, and why it is better in this case to denote it by the term “effective” pair potential.

As illustrated by Eq. (7), empirical potentials have a great flexibility since specific terms may be added if needed. When electrostatic interactions are important, a Coulomb charge–charge interaction may, for instance, be included in the form:

$$U_{zz}(r_{ij}) = \frac{z_i z_j}{4\pi\epsilon_0 r_{ij}}, \quad (8)$$

where z_i, z_j , and ϵ_0 are the charge on atom i and j and the permittivity of free space. Because the Coulombic series converges very slowly, the Ewald, particle-mesh, or multi-pole techniques are used in periodic systems. Likewise, more complex models implement three- and four-body terms to reproduce bond-bending and torsional forces, respectively. Alternatively, polarizable or shell models are employed to consider ions as nonrigid entities and, thus, to account for the effects of the deformation of electron clouds with suitable additional parameters.

From a practical standpoint, the parameters of equations such as (4–7) can be estimated in two different ways depending on the nature of the data to which they are fitted [4]. In the most rigorous way, one relies on energy profiles determined in first-principles calculations or quantum-mechanical simulations of appropriate reference systems (cf. Chapter 2.7). Alternatively, potential energy parameters are fitted through MD or lattice dynamics calculations to some selected physical properties. Structural and elastic data are generally chosen because they are most directly related to interatomic potentials. Thermal properties may also be used, but they are sensitive to second-order effects such as anharmonicity and are in turn generally predicted less accurately.

3 Monte-Carlo Simulations

3.1 Principles of the Method

First described for atomistic simulations in 1953 by Metropolis et al. [7], the MC method cannot account

for the time evolution of the system investigated. By calculating instead its physical properties from repeated samplings made on the basis of a Boltzmann energy distribution of equilibrium states, it differs from a search algorithm with which the energy of the system would occasionally increase even though a steady decrease would be sought after at every step. As already stated, the method is thus inappropriate to tackle any nonequilibrium or history-dependent phenomenon. Over MD simulations, its main advantage is to shorten the calculation time needed to arrive at the equilibrium structure if a suitable sampling method is employed.

Within the framework of the canonical ensemble, the partition function $Q(N, V, T)$ is, for example,

$$Q(N, V, T) = \frac{1}{((\Lambda^3)^N N!) \int d\mathbf{r}^N \exp[-\beta U_p(\mathbf{r}^N)]}, \quad (9)$$

where $\Lambda = \sqrt{h^2/(2\pi m k_B T)}$ is the thermal de Broglie wavelength, β the reciprocal temperature ($1/k_B T$), and $N, \mathbf{r}, U_p, m, k_B$, and T are the number of atoms, atomic coordinates, potential energy of a system, atomic mass, Boltzmann’s constant, and temperature, respectively.

From the partition function it follows that the probability (P) of finding a configuration $\mathbf{r}^N$ is

$$P(\mathbf{r}^N) \propto \exp[-U_p(\mathbf{r}^N)]. \quad (10)$$

To fulfill Eq. (9), the standard Metropolis procedure in MC simulations consists of

- 1) setting up an initial configuration in a periodic boundary cell,
- 2) calculating the energy of this configuration,
- 3) selecting an atom at random and moving it randomly along all coordinate directions,
- 4) accepting the new configuration resulting from the move if it lowers the energy of the system, because the new state is more probable than the former, but keeping the former configuration otherwise only in case its Boltzmann factor is higher than a real number drawn randomly between 0 and 1.

In other words, the MC method does not weight configurations selected randomly according to their Boltzmann factor to calculate the properties of the system, as was done earlier, but weight evenly instead configurations selected with the probability $\exp[-U_p(\mathbf{r}^N)]$. Its trick thus is to concentrate on the sampling in the regions of the phase space that contribute the most to the partition function. Although they will not be described here, there are several other sampling methods in the standard MC calculations to accelerate convergence to the equilibrium state [3].

3.2 Reverse Monte-Carlo Simulations

To complement standard MC simulations, the so-called reverse Monte-Carlo (RMC) method has been developed to study disordered structures [8]. It enables three-dimensional structural models to be constructed in a manner consistent with experimental results. The data most commonly used are PDF and their Fourier transforms obtained from diffraction experiments (Chapter 2.2). In RMC calculations the standard procedure is to

- 1) set up an initial configuration in a periodic boundary cell,
- 2) calculate the set of quantities relevant to the experimental data considered (e.g. PDF),
- 3) calculate the mean square deviations χ^2 of the calculated from the observed results

$$\chi^2 = \frac{\sum (y_{\text{obs}} - y_{\text{cal}})^2}{\rho^2}, \quad (11)$$

where ρ is an appropriate measure of experimental accuracy,

- 4) select an atom and give it a random displacement,
- 5) accept the move if it leads to a χ^2 decrease, but keep the former configuration otherwise,
- 6) repeat from 2) to 5).

To quote a single example, the structural role of “insufficient” network formers has been successfully studied by RMC in a simulation of the atomic configuration of Mg_2SiO_4 glass in which the measured total structural factors were well fitted [9]. The estimated bond distance of

Figure 3 As defined by Eq. (20), total correlation functions $T(r)$ of Mg_2SiO_4 glass (a) and crystal (b) [9].

Mg-O differs in the glass and in the crystal (Figure 3), whereas the difference in the peak position of Mg-O between the two phases reflects the structural feature the glass network is built by the corner- and edge-sharing of highly distorted Mg-O -bearing species.

The advantage of the RMC method is that knowledge of interatomic potentials is not required, but its drawback is that it is not applicable to novel glass systems for which no experimental data can be compared with model values. Besides, there is a risk of arriving at an incorrect structure if the iterative procedure leads to a local, and not to the true minimum of χ^2 . A simple way to avoid such a pitfall is to add a set of effective constraints on bond lengths, bond angles, or coordination numbers (CN) that will prevent spurious results from being obtained.

4 Molecular Dynamics Simulations

The main advantage of MD simulation is to provide important structural information that complements conclusions drawn from experimental studies. One such important result was the demonstration that the structure of sodium silicate glasses fits the modified random network model because the spatial distribution of sodium ions showed a clustering tendency [10]. The result was especially significant as the extremely high fictive temperatures of glasses quenched in MD simulations strongly favor a much more random distribution.

For such reasons, MD simulations have become the most popular method to study theoretically glass and liquid structures (e.g. [11, 12]). Their main advantage is to yield from the three-dimensional coordinates calculated for all atoms a variety of structural information that can often be checked against experimental data. In addition, they also provide information that escape experimental determinations and may thus point to the existence of unknown structural features.

Since they deal with the instantaneous state of a system, MD simulations rest on the Lagrangian function $L(r, \dot{r})$ of coordinates r and their time derivatives $\dot{r}$ as defined in terms of kinetic (K) and potential (U_p) energies

$$L = K - U_p \quad (12)$$

and on the Lagrangian equations of motion

$$\frac{d(\partial L / \partial \dot{r})}{dt} - \left(\frac{\partial L}{\partial r} \right) = 0. \quad (13)$$

This leads to

$$m(i)\ddot{r} = f(i), \quad (14)$$

where $m(i)$ is the mass of atom i and

$$f(i) = \nabla_{r(i)} L = \nabla_{r(i)} U_p, \quad (15)$$

where $f(i)$ is the force exerted on atom i .

If the coordinates of all atoms are known at time t_0 , all the forces exerted and the resulting velocities are calculated with Eq. (15) and then Eq. (14). All the velocities and coordinates after a time step of Δt are updated by the time integration of the equations of motion (14).

When MD methods are applied to glass or disordered systems, several important points should be noted:

- 1) As the proper choice of the interaction potential model is extremely important, a model with complex interaction potentials may be required if any dynamic structure or property is to be calculated after along with the static structure.
- 2) The particular starting configuration is not important as long as equilibration time steps are numerous enough at high temperature. Almost the same structural information should be obtained from different initial configurations. If not, the calculated results are unreliable.

Advanced techniques may be used to calculate structure and properties more efficiently. To omit unimportant contributions to the dynamics, one can, for example, keep constant bond lengths such as O—H during the MD calculation. As an alternative to this *dynamic constraint* method, one can use nonequilibrium MD, which is especially efficient to calculate transport properties such as viscosity. Unlike with conventional MD, a continual friction force can be imposed on the system and its response be monitored.

5 Modeling: Simulation Techniques and Examples

5.1 Overall Glass Structure

In atomistic simulations the positional correlation of atoms is easily investigated within a radius of half of simulation cell size (~ 25 Å). The most widely derived results are the PDF, the RDF, or total correlation function, $T(r)$, which can be readily compared with those obtained in diffraction studies.

In simulations, the PDF and the RDF are derived as follows. The single and pair (two-body) probability density $P_N^{(1)}$, $P_N^{(2)}$ are defined as

$$P_N^{(1)}(r) = \langle \sum_i \delta(r - r_i) \rangle \quad (16)$$

$$P_N^{(2)}(r, r') = \langle \sum_i \sum_{j(j \neq i)} \delta(r - r_i) \delta(r' - r_j) \rangle, \quad (17)$$

where N is again the number of atoms and r_i is the coordinate of atom i .

The value of $P_N^{(1)}(r)$ in homogeneous system turns out to be the number density ρ , which is defined as N/V , where V is the volume.

Moreover, $P_N^{(2)}(r)$ is expressed in terms of the PDF, $g(r, r')$, and number density ρ as:

$$P_N^{(2)}(r, r') = \rho^2 g(r, r'). \quad (18)$$

As to the RDF, $J(r)$, it is defined as the number of atoms between r and $r + dr$ from the center of an arbitrary origin atom:

$$J(r) = 4\pi r^2 g(r, r'). \quad (19)$$

An alternative function called total distribution function, $T(r)$, is calculated as:

$$T(r) = 4\pi \rho r g(r, r'). \quad (20)$$

The information directly obtained from diffraction experiments is the intensity $I(Q)$, which is related to $J(r)$ by

$$J(r) = 1 + \left\{ \frac{1}{(2\pi^2 \rho)} \right\} \int Q I(Q) \sin(Qr) dQ. \quad (21)$$

Finally, the frequently used structure factor, $S(Q)$, is the Fourier transform of the number density ρ_Q first calculated in atomistic simulation:

$$\rho_Q = \sum_i \exp(-iQ r_i). \quad (22)$$

Then, $S(Q)$ is calculated from ρ_Q :

$$S(Q) = \langle \rho_Q \rho_{-Q} \rangle. \quad (23)$$

It is quite important to reproduce the experimental $J(r)$ in the real space domain or $I(Q)$ in the wave-number domain to validate the calculated three-dimensional structure.

Depending on the atoms considered, X-ray and neutron diffraction experiments can yield different profiles so that both kinds of profiles should be calculated and compared with the relevant data as done in Figures 4 and 5 for MD-simulated B_2O_3 glass [6]. Once the total correlation and interference functions have been validated, more detailed analysis based on PDF functions can be performed, as shown in Figure 6, and important insight into structural order be obtained. Although the experimental peak positions are reproduced reasonably well by the calculated $T(r)$ and $Q I(Q)$, there are some discrepancies for the peak values. The position and width of the first peak represent the average length and the length distribution of B—O bonds, respectively. The second peak position and peak curve are mostly affected bond angles of O—B—O and B—O—B and size distributions. As indicated by a detailed analysis of the data, most of the discrepancy is due to a simulated fraction of only 30–50% for the so-called boroxol B_3O_6 rings (cf. Chapter 7.6) compared to the 60–80% range of the experimental values [13].

Figure 4 Comparisons between the experimental [13] and simulated [6] X-ray (a) and neutron (b) total correlation functions of B_2O_3 glass.

5.2 Short-range Order

Of particular interest for characterizing short-range order are CN. In atomistic simulation, this parameter is well defined as the number of atoms falling within a given distance from an arbitrary atom. For each atomic pair this cutoff radius is typically estimated either from the corresponding bond lengths in crystal structures or from the position of minimum between the first and second peaks of the pair-distribution function. Alternatively, the CN can be estimated experimentally from the height of the first peak observed in the X-ray diffraction or neutron diffraction spectra or from the chemical and isomer shifts in NMR or Mössbauer spectra, respectively. In MD studies the oxygen CN of network-forming cations (Si, B, P, Ge, etc.) are generally calculated to be within 5% of the experimental data even for the changes with varying pressure or concentration of network-modifier alkali or alkaline earth cations. Such coordination changes from 3 to 4 for B atoms in borate glasses and from 4 to 6 for Si and Ge in silicate and germanate glasses have been well documented in this way (e.g. [12]).

On the other hand, the oxygen CN is not well defined for intermediate network-forming cation (Al, Fe, Zr, etc.) or network-modifier cations when the distance

Figure 5 Comparisons between the experimental [13] and simulated [6] X-ray (a) and neutron (b) interference functions of B_2O_3 glass.

distribution between cation and oxygen atom is broad. A slight change in the definition of cutoff radius then translates in a large change in CN. In MD simulations on sodium aluminosilicate glasses, the switch of Al from a network-forming to a network-modifying role has nonetheless been evidenced by a CN increase from six in crystal to four and five in glass (e.g. [14]) whereas the existence of fivefold coordinated aluminum and threefold coordinated oxygens has also been evidenced [15].

In silicate glasses another fundamental feature to describe variations of structure and properties is the “ Q_n distribution,” where the subscript n indicates the number of bridging oxygen (BO) in an SiO_4 tetrahedra (Chapter 2.3). In MD simulations it is easy to identify nonbridging oxygens (NBO) on the basis of the cutoff radius. The calculated Q_n distributions for sodium-silicate glasses have been compared with that determined by MAS-NMR experiments [16]. The MD calculations reproduce the experiments reasonably, although the extremely rapid quenching rates prevailing in the MD simulation may broaden the distribution, which does depend on actual T, P conditions. The analysis of Q_n is also important for phosphate glasses, because Q_n

Figure 6 PDF functions in simulated B_2O_3 glass and their structural assignments [6]. The peaks labeled in (a) refer to the specific distances indicated in the elementary structural units (b).

distribution reflects their polymer-like structure that results from the existence of doubly bonded oxygen atoms. In the case of phosphate glass not many MD studies have been published and more validated potential models need to be developed. Recent MD calculations on iron phosphate glasses have demonstrated that the network connectivity is indeed dominated by the expected Q_n [11].

The third useful information on short-range order is the “bond angle distribution” (BAD), because the nature of the existing polyhedral units can be ascertained from oxygen–cation–oxygen angles. For SiO_2 and silicate glass, the simulated peak position is, for instance, found near 109.47° in O–Si–O angle distributions, which of course reflects the presence of Si within SiO_4 tetrahedra. Likewise, the peak of O–B–O angles in B_2O_3 lies around 120° , in harmony with the formation of BO_3 triangles (Figure 7). As for the B–O–B distribution, a significant amount of angles with 120° reveals the presence of boroxol rings (Figure 7) because, without boroxol rings, the B–O–B distribution should be around 129° as observed in B_2O_3 crystal [6]. In this respect, the interest of MD simulations stems from the fact that there is no direct method for determining the BAD experimentally – just a possibility to estimate roughly average values from X-ray or neutron diffraction data. These simulated cation–oxygen–cation BADs are specially valuable to probe

Figure 7 Bond angle distribution in simulated B_2O_3 glass.

local structural changes with either temperature or pressure in single-component glasses such as SiO_2 , B_2O_3 , P_2O_5 , or GeO_2 .

The fourth information of interest is the “torsion angle distribution” (TAD), to which particular attention is paid for polymers whose structure and properties are significantly affected by the twisted arrangement of side chains. Again, B_2O_3 glass illustrates the relevance of this distribution to inorganic glasses because of the steric problem raised by the interconnection of BO_3 units and boroxol B_3O_6 rings (Figure 8). In this case, the calculated TAD suggests different connecting geometries between BO_3 – BO_3 linkages and B_3O_6 – B_3O_6 units: the former are preferentially oriented in a perpendicular direction, which means that connected BO_3 units do not lie in the same plane, whereas the latter are oriented in the same direction, which means that B_3O_6 units do lie in the same plane [6]. For SiO_2 glass, no such distinction is of course found, but MD simulations do suggest that a torsional transformation takes place between neighboring SiO_4 tetrahedra at elevated temperature, in analogy with the structural changes associated with the α – β transition in cristobalite [17]. In addition, it has been suggested that the abrupt rotation of Si–O–Si equivalent to torsion movement between two SiO_4 tetrahedra is the cause of anomalous thermomechanical properties in silica glass [17].

5.3 Medium-range Order

Medium-range order is difficult to study either experimentally or through numerical simulations. The size distribution of rings made up of cations and oxygen atoms is in particular an important parameter when investigating geometrical features in the 5–15 Å range. Usually a ring is characterized by the number of its network-forming cations, which can be derived from the calculated atomic coordinates as shown in Figure 9 for simulated B_2O_3 and SiO_2 glasses. Compared with cristobalite, tridymite, and quartz, whose ring sizes are 6, 6, and 6 and 8, respectively, simulated SiO_2 glass shows a broad distribution around 6.

Figure 8 Torsion angle distribution in simulated B_2O_3 glass between BO_3 and BO_3 units (a) and between B_3O_6 and B_3O_6 units (b) [6]. Data sampled at 0 K to prevent peaks from being blurred by atomic vibrations.

Figure 9 Ring size distribution in simulated B_2O_3 and SiO_2 glasses [11]. Data sampled at 0 K.

It has been speculated that the existence of sizes of odd-numbered rings are characteristic of disordered structures and might impede glass crystallization, because five-fold rotational symmetry does not exist in crystals where four-, six-, and eight-membered rings are primarily observed. In B_2O_3 glass, which is extremely reluctant to crystallize, the existence of B_3O_6 units indeed causes the presence of a peak at 3 in the ring statistics.

Of more general relevance is the vibrational density of states (VDOS). One can calculate it by solving the eigenvalue problem once the curvature of the energy surface

Figure 10 Vibrational density of states in simulated B_2O_3 glass [6]. See text for the assignments of the peaks labeled A, B, and C.

around the stable configuration is obtained. The VDOS for simulated B_2O_3 glass is shown in Figure 10, where the peaks labeled A, B, and C represent the vibrations associated with independent BO_3 units observed in crystalline B_2O_3 , where B_3O_6 units are absent, the breathing mode of B_3O_6 units observed in the crystal of metaboric acid comprised of B_3O_6 unit, and the vibrations of $B_3O_6 + n$ units with several BO_4 tetrahedra comprised in rings [6], respectively. The VDOS can thus provide important structural information in terms of cooperative motion of structural units.

There is another geometrical method relying on the so-called “Voronoi diagram” (e.g. [18]). It is largely employed for monatomic system for which partitioning three-dimensional space is simple and easy when the calculated atomic coordinates obtained by atomistic simulations are used to delineate the portion of space assigned to every atom. These “Voronoi polyhedra” are then characterized by their numbers of faces and corners whose distributions change as positional relationships vary in the glass structure. The other geometrical method is called the analysis of “bond orientational order.” The order parameter that is rotationally invariant can be calculated with spherical harmonic functions. This order parameter has been used to investigate a local icosahedral order chiefly for monatomic system, because its value can discriminate geometrical differences between FCC, HCP, icosahedral, and BCC clusters (e.g. [18]).

In summary, atomistic simulations provide a key to explaining the concept of “modified random network theory [10]” in alkaline silicate glass [10] or the existence of “super-structural units [19]” in B_2O_3 glass [6]. However, new analytical methods are required to understand medium-range order in more detail.

5.4 Structure-related Properties

Important thermodynamic properties can be calculated once numerical simulations have yielded atomic

configurations and velocities. The pressure is, for example, calculated from

$$P_{ij} = \left(\frac{N}{V}\right)kT - \frac{1}{(3V)} \left\langle \sum_i \sum_{j(i \neq j)} f_{ij} r_{ij} \right\rangle, \quad (24)$$

where the bracket indicates an equilibrium time average and N , V , T , f_{ij} , and r_{ij} are as usual the number of atoms, cell volume, temperature, and pair force and distance between atoms i and j , respectively.

The internal energy (E_{int}) is

$$E_{\text{int}} = \left(\frac{3}{2}\right)kT + \left\langle \sum_i \sum_{j(i \neq j)} f_{ij} r_{ij} \right\rangle, \quad (25)$$

and the molar heat capacity at constant volume (C_v):

$$C_v = \left(\frac{\partial E_{\text{int}}}{\partial T}\right)_V. \quad (26)$$

Alternatively, one can derive C_v from the potential energy fluctuations through

$$\langle U_p^2 \rangle - \langle U_p \rangle^2 = \left(\frac{2}{3}\right)Nk^2T^2 \left(\frac{1 - (3/2)k}{C_v}\right) \quad (27)$$

and two other interesting properties are the thermal expansion coefficient, (α_p)

$$\alpha_p = \left(\frac{1}{V}\right) \left(\frac{\partial V}{\partial T}\right)_p = \left(\frac{1}{T}\right) \left\{ 1 - \left(\frac{1}{V}\right) \left(\frac{\partial H}{\partial p}\right)_T \right\}, \quad (28)$$

where H is enthalpy, and the thermal pressure coefficient (β_V):

$$\beta_V = \left(\frac{\partial p}{\partial T}\right)_V = \left(\frac{1}{T}\right) \left\{ \left(\frac{\partial E_{\text{int}}}{\partial V}\right)_T + P \right\}. \quad (29)$$

After a model of atomistic simulation is validated so that it can reproduce static structure of glass, it can be applied to investigate transport and dynamical properties such as diffusion constants, viscosity, or the Van Hove correlation function (Chapter 4.6).

5.5 Experimental and Computational Complementarity

The static arrangement of structural units for B_2O_3 glass and the dynamical arrangement of structural units for SiO_2 glass represent new insights on glass structure provided by MD simulations, in these cases, by the TAD, which escape any experimental determinations. These two examples thus illustrate the complementary nature of numerical simulations and experimental studies of glass structure. When the history of structural studies on glass is looked back on, it is clear that both diffraction and spectroscopic studies have made fundamental

contributions to the construction of structural models. The RDF or the PDF can indeed be readily calculated from the Fourier transform of experimental X-ray, neutron, or electron diffraction data (Chapter 2.2). Because this type of information represents averaged one-dimensional structural data, however, there is always some arbitrariness when reconstructing the actual three-dimensional configuration in which one is interested.

Other probes such as IR, Raman, or NMR spectroscopies can provide information only on short-range order in glass structure. In contrast, atomistic simulations do provide realistic three-dimensional configuration directly as long as an appropriate atomistic model is employed. One could confidently argue that a structural model of glass is reliable when the model matches the results of both experiments and atomistic simulations. In summary, the relation between atomistic simulation and experiment is complementary because both methodologies provide insights on different aspects of glass structure. Atomistic simulations nonetheless possess two other advantages over experimental methods. The first is that they can determine three-dimensional configurations from short- to medium-range order extending up to the size of cell length (10–100 nm). The second is that a very broad range of atomistic simulations become possible as soon as an appropriate simulation model is established. For example, it is easy to change external conditions such as temperature, pressure, or other external forces to investigate their effects on structure. And physical and chemical properties can be readily derived from the potential-energy and structural models with standard statistical mechanical methods.

6 Perspectives

Development of both faster computing processors and efficient simulation algorithms have expanded the range of atomistic simulations and narrowed down their discrepancies with experiments. Simulations would nonetheless benefit from improved accuracy. As becoming more common, the best way to achieve this goal is to perform first-principles MD calculation from beginning to end. Although such calculations made with standard quantum mechanical codes remain difficult when dealing with a large number of atoms, progress should result from the use of the so-called order- N and linear scaling methods, which have developed vigorously during the past decade. For oxide glasses, recent codes such as SIESTA or CONQUEST now have the potential ability to handle systems of around one thousand atoms with a supercomputer whereas calculations for systems ten times bigger should

become feasible in the next decade. Alternatively, better classical potentials can be derived from the energy data yielded by *ab-initio* methods as well illustrated by the Tuneyuki and BKS potentials used for silica glass that were based on the simple Buckingham function [4]. Whereas parameter fitting of these potential models was handmade, automatic fitting by machine learning methods is becoming popular since a huge number of data can be sampled on potential energy surfaces yielded by first-principles calculations to derive better interatomic potentials. And even if the simulation remains based on classical mechanics, the shell, polarizable, charge-equilibrium, and other models will be more widely used to reproduce better structures and properties [4].

The two other main limitations of numerical simulations currently concern the space- and timescales considered. To cope with them, combinations of two different techniques may be used as already described in Section 3 for RMC methods. Besides, MC algorithms can be integrated into MD calculations to speed up simulation of too slow structural relaxation as is the case for the formation of boroxol rings in B_2O_3 [11]. Of more general use, however, is a combination of classical and first-principles MD simulations [20] whereby the former yield a preliminary structure that is subsequently optimized in the latter before spectroscopic or other properties are finally derived from the first-principles simulations.

The “coarse-graining” methods are also promising as multi-scale simulation procedures. By lumping groups of atoms into larger entities referred to as particles, which interact according to newly parametrized effective interaction potentials, they have been successfully used for polymers to describe slow dynamic modes and to investigate the cooperative motions and fluctuations observed in the intermediate- and long-range regions. For oxide glasses, however, their application is hampered by the difficulty of assigning appropriate structural fragments to coarse-grained units.

Finally, it is important for glass scientists to share their know-how on simulation techniques and interatomic potentials. One of such activities takes place in the TC-3 Technical committee of the International Commission on Glass (ICG) where round-robin tests are made to compare experimental data and calculated results on standard glass samples. Such an activity will provide useful information to other glass scientists on agreement and discrepancy between experiments and atomic simulations. Another activity is conducted in TC-27 whose members discuss future directions of atomistic simulations, promote standardization of atomistic techniques, and provide information on these techniques to the glass community (e.g. [21]). In addition, ICG has published an educational

textbook, which includes one chapter on atomistic simulations [22].

In a near future, we strongly expect that any macroscopic property will be explained in terms of microscopic structure by atomistic and first-principles simulations. In addition, computational design of glass materials will advance rapidly in good harmony with experimental studies.

First-principles Simulations of Glass-formers

Walter Kob and Simona Ispas

Laboratoire Charles Coulomb (L2C), University of Montpellier, CNRS, Montpellier, France

1 Introduction

In their early days, i.e. in 1940–1950, computer simulations were mainly done to address questions in statistical physics, such as the properties of hard-sphere systems or the dynamics of simple crystals [1]. When a few decades later computers became more powerful and more accessible, it became possible to study the properties of real materials. For this, researchers used an approach that today is referred to as classical molecular dynamics (MD), i.e. the interactions between the particles that constitute the material are described by an effective potential with a form chosen in a rather ad hoc manner, e.g. Lennard-Jones. The parameters of the potential (e.g. the depth and the position of the well in the Lennard-Jones potential) are selected such that the density, the melting temperature for a crystal, or other macroscopic properties of the simulated system matches experimental data. Once these interactions are known, one solves numerically Newton's equations of motion and hence obtains the trajectories of all the particles (Chapter 2.8, [1]). From these trajectories, one then can determine physical properties of the system such as the radial distribution function, diffusion coefficients, or elastic constants.

Although simulation studies with effective potentials are very valuable to gain qualitative insight into the properties of liquids and solids, they usually do not allow to obtain a good quantitative description. The reason for this failure is that most properties depend in a quite sensitive manner on the potential that describes the interactions between the constituting particles of the material. Since normally these interactions depend not only on the type of atoms considered but also on the microscopic

environment of the particles (e.g. the bond strength between an oxygen and a silicon will change if a hydrogen is approached to this pair), it is basically impossible to come up with a simple potential-energy expression that could describe faithfully all these different environments. This problem is particularly pronounced for glasses where, in contrast to crystals, each atomic species has multiple local environments. At present, the only method that can address this problem in a systematic manner is the *ab initio* formalism (also called first-principles). In this approach one does not rely on a fixed functional form for the interaction potential, but uses instead the electronic degrees of freedom of all atoms to compute the forces acting on them in the system. Once these forces are known, one solves Newton's equation of motion to determine the trajectory of the particles and, subsequently, the properties of the system. Thus *a priori* the only input needed for these simulations are the species of the particles, a feature that has allowed *ab initio* simulations to become a highly attractive method to gain a detailed understanding of the properties of glass-forming liquids and glasses.

The goal of this review is to give a brief introduction to the method, discuss its advantages but also its problems, and then to present some specific examples showing that this type of simulation is indeed very useful to improve our understanding of glasses at the microscopic scale. We will first focus on structural properties in view of the major problems caused by atomic disorder, especially in complex glasses. Vibrational properties will then be examined as the heat capacity, thermal conductivity, or transparency directly or indirectly depends on them. Because solid-state nuclear magnetic resonance (NMR) yields detailed insights into the local structure of materials (Chapters 2.2 and 2.4), especially when long-range symmetry is lacking, we will conclude this chapter with a brief description of the calculation of NMR spectra.

2 Ab Initio Simulations

2.1 General Principles

In the ab initio approach, the forces on the atoms are obtained from the electronic degrees of freedom of the system as determined from the Schrödinger equation,

$$\mathcal{H}_e \Psi = E \Psi, \quad (1)$$

where the (complex) many-electron wavefunction $\Psi(\{\mathbf{r}_i\}; \{\mathbf{R}_J\})$ depends on the positions of the n electrons, $\{\mathbf{r}_i\}$, as well as the positions of the N nuclei, $\{\mathbf{R}_J\}$ [2], E is the energy of the electronic degrees of freedom, and the operator $\mathcal{H}_e$ is given by

$$\mathcal{H}_e = - \sum_{i=1}^n \frac{1}{2} \nabla_i^2 + \sum_{\substack{i,j=1 \\ j < i}}^n \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} + \sum_{i=1}^n \sum_{I=1}^N \frac{Z_I}{|\mathbf{r}_i - \mathbf{R}_I|}, \quad (2)$$

with Z_I the charge of ion I . This equation is written in atomic units, i.e. Planck's constant, the electronic charge and mass are set to unity, and the Laplacian ∇^2 is given by $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$. In Eq. (1), only the electronic degrees of freedom are treated quantum mechanically whereas those of the nuclei are not. This approximation, often called “Born–Oppenheimer” or “adiabatic,” is quite accurate since the mass of the electron is almost 2000 times smaller than the one of the lightest nucleus, i.e. hydrogen. Hence, the degrees of freedom of the electrons are basically decoupled from those of the nuclei, i.e. the heavy nuclei move more slowly than the light electrons which thus adapt instantaneously to the changes of the nuclear positions. As a consequence, one assumes for the electronic structure calculations that the nuclei are clamped at fixed positions and that hence the electronic wavefunction Ψ depends on $\{\mathbf{R}_J\}$ only parametrically [2].

To reduce the computational complexity, even further one considers only the ground-state solution of Eq. (1), Ψ_0 , i.e. the electronic state with the lowest energy, which is in fact the only one that matters even for melts at high temperatures. The interaction potential between the nuclei is then given by $\Phi(\{\mathbf{R}_J\}) = \langle \Psi_0 | \mathcal{H}_e | \Psi_0 \rangle + \sum_{I,J=1, I < J}^N \frac{Z_I Z_J}{|\mathbf{R}_I - \mathbf{R}_J|}$ and the force on particle I is given by $F_I = -\nabla_I \Phi(\{\mathbf{R}_J\})$ [2].

Finding the wavefunction Ψ_0 that is the solution of the Schrödinger equation (1) is a formidable task and there are two main approaches to solve it. The first one is a wavefunction-based method, often known as the quantum-chemistry approach, which starts from the Hartree–Fock method. In a first-order approximation, it factorizes the many-body electronic wavefunction into

one-particle wavefunctions whose ground states are then searched numerically. Although at present the solution is found in a reasonable amount of time for several tens of atoms, new methods have been proposed in this field with very promising results for systems ten times bigger. The second method, which will now be described in some detail, is the density functional theory (DFT).

2.2 Density Functional Theory

The DFT formalism exploits certain ground-state properties of many-electron systems in an external field, thus in our case the Coulomb field of the nuclei. Following up ideas proposed by Thomas and Fermi in the 1930s, it has been rigorously established by Hohenberg, Kohn, and Sham in the early 1960s [2], who showed that the total energy of the system is a functional of the electronic density. DFT gets rid of the many-body wavefunction, which depends on $3n$ electronic spatial coordinates, and replaces it by the simpler electronic density $\rho(\mathbf{r})$ that only depends on three spatial coordinates:

$$\rho(\mathbf{r}) = \int \dots \int d\mathbf{r}_2 \dots d\mathbf{r}_n \Psi_0^*(\mathbf{r}, \mathbf{r}_2, \dots, \mathbf{r}_n) \Psi_0(\mathbf{r}, \mathbf{r}_2, \dots, \mathbf{r}_n). \quad (3)$$

Kohn and Sham [3] showed that this density can be written as a sum of the density of noninteracting particles, $\rho(\mathbf{r}) = \sum_i^n |\phi_i(\mathbf{r})|^2$, where ϕ_i are the fictitious one-particle Kohn–Sham (KS) orbitals, and thus the ground-state density $\rho_0(r)$ is given by the sum of the ground states of these particles. Hence, the total energy of the system can be expressed as

$$E_{\text{KS}}[\rho] = T[\rho] + \int d\mathbf{r} \rho(\mathbf{r}) \left[\frac{1}{2} \int d\mathbf{r}' \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} - \sum_I \frac{Z_I}{|\mathbf{r}_i - \mathbf{R}_I|} \right] + E_{\text{xc}}[\rho], \quad (4)$$

where $T[\rho]$ is the kinetic energy of a system of n noninteracting electrons having the density ρ ,

$T = -\frac{1}{2} \sum_{i=1}^n \int d\mathbf{r} \phi_i^*(\mathbf{r}) \nabla^2 \phi_i(\mathbf{r})$, and the second term is the Coulomb interactions between electron–electron and electron–nuclei. The third term is the so-called exchange and correlation energy which accounts for all quantum many-body effects due to the Pauli exclusion principle which correlates electrons. Since this term cannot be evaluated exactly, approximations have to be made. Even though $E_{\text{xc}}[\rho]$ is usually substantially smaller than the two other terms, the manner it is approximated may become crucial for chemically complex systems [2].

The simplest one, proposed originally by Kohn and Sham [3], relies on the assumption that at each point the exchange-correlation energy density corresponds to that of a homogeneous gas of electrons. This approximation is called the “local density approximation” (LDA) and is given by:

$$E_{xc}^{LDA}[\rho(\mathbf{r})] = \int d\mathbf{r} \rho(\mathbf{r}) \epsilon_{xc}^{LDA}[\rho(\mathbf{r})]. \quad (5)$$

Even for such a simple model system, the expression of the correlation energy has to be calculated numerically with Monte-Carlo methods. A more advanced approximation, the so-called “generalized gradient approximation” or GGA, is based on a more complex operator making use of the density gradient of m th order:

$$E_{xc}^{GGA}[\rho(\mathbf{r})] = \int d\mathbf{r} \rho(\mathbf{r}) \epsilon_{xc}^{GGA}[\rho(\mathbf{r}); \nabla^m \rho(\mathbf{r})]. \quad (6)$$

However, this higher approximation does not necessarily give more reliable results so that it is a priori not clear which exchange-correlation functional should be used [2]. Despite this problem one can say that the KS approach and reasonable (simple) approximations for the exchange-correlation term have opened the door to the calculations of the electronic structure for many-atom systems relevant to the study of real materials.

Although expressing the full quantum mechanical problem in the language of DFT leads to a significant reduction of the computational effort for calculating the forces on the nuclei, in practice this task is still extremely demanding when dealing with more than a few tens of atoms. Therefore, one usually makes the further approximation that all the core electrons of an atom are lumped together so that their effect is replaced by an effective potential, the so-called “pseudo-potential,” for the remaining valence electrons which are described by a pseudo-wavefunction [2]. The physical motivation for this approximation is that the chemical bonds between two atoms are usually related to the outer valence electrons and thus depend only weakly on the inner core electrons.

2.3 Computational Limitations

So far, we have discussed how DFT allows one to obtain the forces between the nuclei due to their surrounding electrons. These forces can now be used to solve the equations of motion for the nuclei:

$$M_I \ddot{\mathbf{R}}_I = -\nabla_I E_{KS}[\{\phi_i\}, \mathbf{R}], \quad (7)$$

where the energy $E_{KS}[\{\phi_i\}, \mathbf{R}]$ can be calculated from the KS orbitals within the KS scheme of the DFT. In the above equations the nuclei are considered as classical particles

and Eq. (7) is solved using the same methods as in classical MD (see Chapter 2.8 or [1] for details). Because of the resulting motion of the ions, the electronic structure changes and hence one has in principle to recalculate the total energy of the electronic ground state, a procedure that is computationally very costly even within the DFT approach. One possibility to avoid this problem was proposed in a seminal paper by Car and Parrinello in 1985 [4]. The idea behind this so-called Car–Parrinello molecular dynamics (CPMD) is to introduce a fictive dynamics to the electronic degrees of freedom and thus to recast the quantum mechanical problem into a classical one with the electronic wavefunctions as new effective degrees of freedom.

Although the CPMD approach allows to obtain the correct equilibrium properties of a system, the introduction of the fictive dynamics for the electronic degrees of freedom makes that the motion of the system in configuration space is not completely realistic [2]. Despite this shortcoming, CPMD simulations are still widely used to study complex systems by means of computer simulations (cf. software available at <http://www.psi-k.org/codes.shtml>). This problem can, however, be avoided with the so-called Born–Oppenheimer molecular dynamics (BOMD) in which one solves at each time step the electronic problem. This approach thus allows to give a correct dynamics but at the cost of an increased computational load. Only in the last few years the numerical algorithms have been improved to such an extent that today it is possible to simulate within BOMD several hundreds of particles [5, 6].

This brief description of the ab initio simulations should make it clear that in practice the codes for such simulations must be extremely optimized in order to keep the necessary computer time within a reasonable limit. This is why, in contrast to simulations performed with effective potentials, first-principles calculations are not made with “homemade” codes but with one of the very sophisticated and highly optimized packages that have been developed over the years. Various groups use different approaches to maintain and develop these packages, the most popular ones being CPMD, VASP, Quantum Espresso, CP2K, Siesta, CASTEP, etc. (see on <http://www.psi-k.org/codes.shtml> for a more extended list). Each of them has advantages and disadvantages regarding the scaling of computational effort with system size, accuracy, ensembles that can be simulated (microcanonical, canonical, constant pressure, etc.), quantities that can be calculated, etc., and therefore the best choice will depend on the application.

To give an idea of what can be done at present with ab initio simulations, we compare in Table 1 ab initio and classical simulations. Since the computational load for the former does depend on the system considered

Table 1 Comparison of various features of large-scale computer simulations carried out with classical and ab initio methods.

	Classical MD	Ab Initio MD
Size	1 000–500 000 atoms	100–500 atoms
Box size	~100 Å	~15–20 Å
Trajectory length	~1 ns–10 μs	~20–100 ps
Transferability	No	Yes

(owing to the different electronic structure for the atoms), we will consider the example of an oxide glass. We note that, for a given computing time, there is trade-off between the size of the system and the time span covered by the calculation. For a classical system the relevant number is basically the product of the two quantities so that doubling the system size increases the computer time by a factor of two. For ab initio simulations the situation is not that favorable since doubling of the system size usually leads to an increase of the computational load by a factor of 2^α , where α is about 3. As a consequence, system sizes are smaller and accessible timescales are shorter in ab initio than in classical simulations. Therefore, the quench rates used to cool a system from its liquid to its glass state are usually on the order of 10^{13} – 10^{15} K/s. Such rates are thus significantly larger than those of classical simulations (10^{10} – 10^{14} K/s) and of course ways higher than experimental values (10^{-2} – 10^6 K/s). Despite these huge differences, the resulting glasses are surprisingly similar since many of their properties depend only in a logarithmic way on these rates. Therefore, it does make sense to use ab initio simulations to investigate the properties of glasses on the microscopic scale.

3 Structural Properties

In this section we will present some examples to illustrate *how* ab initio simulations can help to gain a better understanding of the local structure of complex glasses. The very first ab initio MD simulations for a glass-former were carried out by Sarnthein et al. in 1995 on silica [7]. Using the Car–Parrinello approach, they generated a glass model by equilibrating for 10 ps a liquid sample with 72 atoms (!) at 3500 K and subsequently quenching it to 300 K. Despite the smallness of the system and the high quench rate (10^{15} K/s!), the resulting glass structure was surprisingly similar to that of the real material with a network of SiO_4 corner-sharing tetrahedra and a neutron structure factor compatible with the that from scattering experiments. These authors also found that their electronic density of states matched well the X-ray

photoelectron spectroscopy data although the predicted band gap of 5.6 eV underestimated the experimental value of about 9 eV, a flaw that often occurs in DFT calculations [2].

This pioneering paper was followed by further investigations in which more complex glass-formers were studied, such as alkali silicate glasses, calcium-alumino-silicates [8–11], and other glass-formers [12, 13]. These investigations allowed to obtain detailed insight into the local arrangement of the atoms, how network modifiers like Na or Ca change these arrangements, and the connections between local structure in real space with structural features as determined in neutron or X-ray scattering experiments.

As an example we will briefly discuss some results obtained for sodium borosilicate of composition 30% Na_2O –10% B_2O_3 –60% SiO_2 (in mol %), an important glass-former in which boron atoms bond to either three or four oxygen neighbors, which makes its structure rather complex, Chapter 7.6, [6]. One important quantity to characterize the structure is the partial radial distribution functions $g_{\alpha\beta}(R)$ which is directly proportional to the probability that two atoms of type α and β are found at a distance r from each other (Chapter 2.2). Thus, this function is defined as [14]

$$g_{\alpha\beta}(R) = \frac{V}{4\pi R^2 N_\alpha (N_\beta - \delta_{\alpha\beta})} \sum_{I=1}^{N_\alpha} \sum_{J=1}^{N_\beta} \langle \delta(R - |\mathbf{R}_I - \mathbf{R}_J|) \rangle, \quad (8)$$

where $\langle \cdot \rangle$ represents the thermal average, V is the volume of the simulation box, N_α is the number of particles of species α , and $\delta_{\alpha\beta}$ is the Kronecker delta.

For the boron-oxygen pair (Figure 1a), the first peak of the radial distribution function is relatively large and slightly asymmetric. By considering three- and fourfold coordinated boron atoms, $^{[3]}\text{B}$ and $^{[4]}\text{B}$, respectively, we can decompose this peak into two contributions and see that the broadening of the total peak is a consequence of the presence of these two populations, the $^{[3]}\text{B}$ –O and $^{[4]}\text{B}$ –O bonds giving rise to the smaller and larger distances, respectively. We can decompose these distributions further by considering the nature of the second nearest neighbor of the central boron atoms, i.e. whether the nearest oxygen is bridging connected to a Si or B atom, or whether it is a non-bridging oxygen. We see that for the case of the $^{[3]}\text{B}$ atoms, the nature of this second nearest neighbor species influences the B–O distance since the position of the corresponding peak depends on the species, whereas this is not the case for the length of the $^{[4]}\text{B}$ –O bonds. The presence of $^{[3]}\text{B}$ and $^{[4]}\text{B}$ units is also reflected in the OBO triplet angle distribution (shown in Figure 1b) by the presence of two peaks.

Figure 1 Contributions of the various structural units of a sodium borosilicate glass to structural features [6]. (a) Distribution of B—O distances around a given B atom as given by the first peak of the partial radial-distribution function. (b) Distribution of the angle formed by two oxygens connected to the same boron.

Although this detailed information is valuable to understand better the local structure of the glass, it is also important to connect the results from the simulation with experimental data. Even if radial distribution functions cannot be directly accessed experimentally, it is possible to measure the static structure factor, which is directly related to the weighted sum of $S_{\alpha\beta}(q)$, the space Fourier transform of $g_{\alpha\beta}(R)$ [14]. For neutron scattering, one finds, for example:

$$S_N(q) = \frac{N}{\sum_{\alpha} N_{\alpha} b_{\alpha}^2} \sum_{\alpha, \beta} b_{\alpha} b_{\beta} S_{\alpha\beta}(q). \quad (9)$$

Here, b_{α} is the neutron scattering length of particles of species α [14] and the partial static structure factors are given by

$$S_{\alpha\beta}(q) = \frac{f_{\alpha\beta}}{N} \sum_{j=1}^{N_{\alpha}} \sum_{K=1}^{N_{\beta}} \langle \exp(i\mathbf{q} \cdot (\mathbf{R}_j - \mathbf{R}_K)) \rangle, \quad (10)$$

Figure 2 Neutron and X-ray structural factors (a and b panel, respectively) for a borosilicate system in the liquid and glass state. Source: From Ref. [6].

where N is the total number of atoms and $f_{\alpha\beta} = 1$ for $\alpha = \beta$ and $f_{\alpha\beta} = 1/2$ otherwise. For X-ray scattering, the relation is

$$S_X(q) = \frac{N}{\sum_{\alpha} N_{\alpha} f_{\alpha}^2(q/4\pi)} \sum_{\alpha, \beta} f_{\alpha}(q/4\pi) f_{\beta}(q/4\pi) S_{\alpha\beta}(q), \quad (11)$$

where $f_{\alpha}(s)$ is the scattering-factor function (also called form factor). Figure 2 shows that even for the same glass sample, $S_N(q)$ and $S_X(q)$ are rather different since both are a *weighted* sum of the partial structure factors, each of which has a multitude of positive and negative peaks. Hence, the resulting sum may show a peak for $S_N(q)$ that is basically absent in $S_X(q)$. Since interpretation of experimental data is further complicated by the fact that one has $k(k+1)/2$ partial structure factors in systems with k species, computer simulations can help to interpret correctly the various peaks if they do reproduce the partial structure factors in terms of peak positions and heights. As a matter of fact, the necessary accuracy is usually ensured only by ab initio simulations.

Another important situation is that of surfaces, for which experimental scattering techniques involving grazing-ray geometries are much less powerful to obtain microscopic information. Because effective potentials are usually developed for bulk systems, their reliability is not guaranteed for surfaces for which the local structure can be very different. One example are two-membered rings in SiO_2 that are present at the surface but absent in the bulk. Hence, *ab initio* simulations are to be preferred for investigating surfaces since they can deal with such heterogeneous geometries.

One interesting example of surface effects is the difference between the interatomic distance and bond-angle distributions of water molecules in the bulk and adsorbed at the surface of amorphous silica (Figure 3). Although

Figure 3 Structural differences between bulk (BW) and surface (SW) water in SiO_2 glass [15]. (a) Water–water radial distribution function. (b) Distribution of the angle θ between the water dipole (bisecting the HOH angle) and the surface normal.

there are no significant differences in the positions of the O—O and O—H peaks (Figure 3a), close to the surface the fluid is less structured than in the bulk as signaled by smaller peaks. Likewise, differences concerning the angle between water dipole (i.e. the bisector of the HOH angle) and the surface normal (Figure 3b) indicate a strong change of the local geometry. Only accurate interaction potentials, such as *ab initio* simulations will be able to pick up these effects.

4 Vibrational Properties

The vibrational density of states (vDOS) $g(\omega)$ is the normalized distribution function of the eigenfrequencies ω_p of the dynamical matrix of the system which is directly related to the second derivative of the potential with respect to the coordinates $\mathbf{R}_i$ and $\mathbf{R}_j$, i.e. $\partial^2 \Phi / (\partial \mathbf{R}_i \partial \mathbf{R}_j)$ for $i, j \in \{x, y, z\}$, thus

$$g(\omega) = \frac{1}{3N-3} \sum_{p=4}^{3N} \delta(\omega - \omega_p), \quad (12)$$

where $3N-3$ is the number of eigenmodes with nonzero frequency. Associated with each eigenfrequency ω_p of the dynamical matrix is an eigenvector $\mathbf{e}_p$ that gives detailed information regarding the particles that oscillate with the frequency ω_p . Studies of $\mathbf{e}_p$ have allowed to gain insight into the nature of the vibrational modes of various materials such as silica and germania glasses [12, 16–18] and more complex systems ([6, 10, 11, 19], Chapter 3.4).

The structure of a solid is related to a balance of the forces between its atoms, i.e. to the first derivative of the potential since these forces must mutually compensate to ensure a mechanically stable equilibrium. In contrast, vibrational properties are related to the curvature of the potential, i.e. to its second derivatives. As a consequence, it is quite hard to find effective potentials that reproduce correctly the experimental vDOS, even for systems as simple as pure silica [20].

The true vDOS given by Eq. (12) is not directly accessible in experiments, in which only an effective vDOS, $G(\omega) = C(\omega)g(\omega)$, can be measured. The function $C(\omega)$ describes how the modes with frequency ω are coupled to the probing radiation (photons, neutrons, etc.). For inelastic neutron-scattering experiments, this function can be derived, within approximations, from the eigenvectors $\mathbf{e}_p$ of the dynamical matrix [21].

In practice, the vibrational properties of a system can be calculated in two different ways. The first is to determine the local potential minimum of the glass structure (i.e. to quench the sample to $T = 0$ K) and then to calculate directly the dynamical matrix, for instance, by a finite-difference scheme for the forces. By diagonalizing this

matrix, one can then obtain its eigenfrequencies and eigenvectors and, hence, $g(\omega)$. The second method consists in running a simulation in which one solves Newton's equations of motion at low temperatures where the harmonic approximation is valid. If one measures the time autocorrelation function of the velocity of a particle, its time Fourier transform is directly proportional to the vDOS. This approach is from the computational point of view cheap, but it has the drawback of not giving any information on the eigenvectors, i.e. on the nature of the motion of the atoms.

The advantages of ab initio over effective pair-potential simulations are illustrated by the neutron-effective vDOS for silica (Figure 4). The effective potentials give a surprisingly good description of the structural properties of real silica [23] and also of the high-frequency vDOS where modes concern intra-tetrahedral excitations [18]. However, the vDOS calculation with the effective potential gives a broad, flat band between 200 and 600 cm^{-1} whereas the ab initio simulations show, in agreement with the experimental data, a marked peak at around 400 cm^{-1} [17].

A further technique used to get insight into the vibrational properties of glasses are measurements of dielectric properties (Chapter 3.4), which are directly related to the local polarizability of the material. Because ab initio simulations do give a good description of polarizability, they allow the high-frequency (ϵ_∞) and static dielectric constant (ϵ_0) to be accessed directly. Also called relative permittivity, the former quantity can be estimated as one third of the trace of the purely electronic dielectric tensor

$(\epsilon_\infty)_{ij} = \delta_{ij} + \frac{4\pi}{V} \frac{\partial^2 E_{\text{tot}}}{\partial \mathcal{E}_i \partial \mathcal{E}_j}$, which describes the reaction of

Figure 4 Effective neutron densities of states for a-SiO₂ as obtained from an ab initio simulation (solid black line) and a simulation with an effective force field (solid blue line), after [17]. Symbols: Data from two neutron scattering experiments [22]. (See electronic version for color figures).

the electrons to the presence of an external electric field if the ions were kept at fixed positions. For a glass, this tensor is basically isotropic and diagonal. The static dielectric constant ϵ_0 reflects the ionic displacement contributions to the dielectric constant and it can be expressed as [24]:

$$\epsilon_0 = \epsilon_\infty + \frac{4\pi}{3V} \sum_p \sum_j \frac{|\mathcal{F}_j^p|^2}{\omega_p}, \quad (13)$$

where p runs over all the eigenmodes, and $\mathcal{F}_j^p$ is the so-called oscillator strength which is defined as

$$\mathcal{F}_j^p = \sum_{I,k} \frac{\mathbf{e}_{I,k}(\omega_p)}{\sqrt{m_I}} Z_{I,jk}. \quad (14)$$

Here, $\mathbf{e}_{I,k}(\omega_p)$ is the part of the eigenvector $\mathbf{e}(\omega_p)$ that contains the three components of particle I , and the quantity $Z_{I,jk}$ is the Born effective charge tensor defined as:

$$Z_{I,ij} = \frac{\partial F_i^I}{e \partial \mathcal{E}_j} \quad I = 1, 2, \dots, N, \quad i, j \in \{x, y, z\}, \quad (15)$$

where e is the elementary charge, i.e. $Z_{I,ij}$ is an effective charge that connects the strength of an external electric field $\mathcal{E}$ to the force F^I on particle I .

These quantities allow to obtain immediately the real and imaginary parts of the dielectric function $\epsilon(\omega) = \epsilon_1(\omega) + i\epsilon_2(\omega)$ [24]:

$$\epsilon_1(\omega) = \epsilon_\infty - \frac{4\pi}{3V} \sum_p \sum_j \frac{|\mathcal{F}_j^p|^2}{\omega^2 - \omega_p^2} \quad (16)$$

$$\epsilon_2(\omega) = \frac{4\pi^2}{3V} \sum_p \sum_j \frac{|\mathcal{F}_j^p|^2}{2\omega_p^2} \delta(\omega - \omega_p). \quad (17)$$

Closely related to $\epsilon(\omega)$ is the absorption spectra $\alpha(\omega)$ which is given by

$$\alpha(\omega) = 4\pi\omega n''(\omega), \quad \text{with } n''(\omega) = \sqrt{\frac{\epsilon_1^2 + \epsilon_2^2 - \epsilon_1}{2}}. \quad (18)$$

All these functions can be measured directly. On one side, they allow to test the predictive power of the simulations and, on the other, they help to interpret the various features found in the experimental spectra. For the infrared spectra of amorphous silica (Figure 5a–c), the theoretical calculation reliably predicts the position of the various peaks although their widths do not match very well the experimental data [18]. For the more complex NBS glass, a broad band is observed below 300 cm^{-1}

Figure 5 (a)–(c): Infrared spectra for amorphous SiO_2 as obtained from ab initio simulations (solid lines) and from experiments (dotted lines) [18]. (d) and (e): Infrared spectra for a sodium borosilicate glass as obtained from ab initio calculations and compared to experimental data for pure SiO_2 and B_2O_3 glasses, as well as for a sodium borosilicate glass with a similar composition [6].

where the vDOS is strongly dominated by the motion of Na atoms [6], which explains why the spectra of alkali-free glass-formers lack such a low-frequency band. In contrast, the narrow band found slightly above 400 cm^{-1} is also present in the spectrum of pure silica where it has been assigned to the bending and rocking motion of oxygen atoms [16]. Therefore, this peak has probably the same origin in NBS as in SiO_2 although it is somewhat broader and shifted to lower frequencies as a result of a more disordered structure.

At high frequencies one finds two bands. The first one, ranging from 850 to 1200 cm^{-1} , can be assigned to oxygen stretching modes of Si–O bonds. That this band lies at lower frequencies than for silica (sharp peak at around 1070 cm^{-1}) is consistent with earlier results showing that the presence of non-bridging oxygen atoms shifts the band to lower frequencies [19]. The second band extends between 1200 and 1600 cm^{-1} , and is due to the motions of

oxygen atoms belonging to $^{[3]}\text{B}$, in agreement with the fact that B_2O_3 , which has mainly $^{[3]}\text{B}$ units, shows a very pronounced peak in this frequency range. Regarding absorption, good agreement is again found between the spectrum of NBS and the ab initio calculations made for a closely related composition (Figure 5d and e). The main deviation is found at high frequency where a peak is absent in the experimental spectrum but present in the simulation, since the latter overestimated the concentration of $^{[3]}\text{B}$ units because of the high quenching rate [6].

Finally, we mention that DFT-based methods have also been proposed in order to compute Raman and hyper-Raman spectra for periodic solids [25, 26]. These approaches have been used to calculate the corresponding spectra for the main oxide network-formers, i.e. SiO_2 , B_2O_3 , or GeO_2 , with a good a very good agreement to experimental data [12, 13, 18].

5 Calculations of NMR Spectra

A serious problem faced by NMR experiments on disordered structures is that the observed peaks may overlap so that real-space interpretations of the spectra are not always straightforward. Theoretical calculations can thus give helpful guidance, but their difficulty is illustrated by the fact that the first NMR schemes have been proposed only 15 years ago. In the glass community, the so-called GIPAW approach proposed by Pickard and Mauri [27] is certainly the most used one, and implemented in many ab initio packages. However, the theory on how this is done is rather involved, see Ref. [28], and therefore we just illustrate the kind of results obtained with calculations of ^{29}Si Magic Angle Spinning spectra done for binary alkali and alkaline earth silicates (Figure 6).

Regarding the peak positions, the agreement between the ab initio simulations and the experimental spectra is remarkably good (Figure 6a). For lithium silicates, slight discrepancies are found for the peak intensities but they are likely due to the modest size and high quenching rates of the simulated samples. In fact, one can handle this problem by determining how the concentrations of the various structural units depend on the cooling rate (or on the temperature of the liquid) and then adjusting them to the actual experimental conditions [6].

Although NMR experiments provide information on the nature of the local structure ($Q^{(n)}$ -species, connectivity of the atoms, etc.) it is difficult to extract direct information on the geometry of the local structures, such as bond angles. That ab initio simulations are also useful for this is demonstrated in Figure 6b where we show the chemical shift as a function of Si–O–T angle, where O is a first nearest neighbor of Si atom and T is the second Si atom bonded to that O. The data clearly show: (i) that there is a linear relationship between this angle and the chemical shift, (ii) that this relationship is basically independent of the composition of the glass, and (iii) that its slope depends on the $Q^{(n)}$ -species of the second Si atom.

6 Perspectives

Ab initio simulations of glasses have now become standard to determine observables of high practical relevance, but usually inaccessible to simulations with effective potentials. Despite their computational cost, they constitute a most useful tool to gain insights into microscopic properties of glasses, especially when their composition is complex, and even to develop novel types of glasses with exotic compositions. Their accuracy makes them most useful when a multitude of possible local atomic

environments coexist either in the bulk or at glass surface or when important structural heterogeneities are found at a microscopic scale. This applies, for instance, to the properties of the charged and neutral defects in amorphous silica, as their presence can strongly affect the performances of electronic and optical devices based on SiO_2 [30]. The technologically important chalcogenide glasses (Chapter 6.5) can only be simulated with force-fields accounting correctly for homopolar bonds, i.e. *ab initio* simulations. Because chalcogenides do not contain oxygen, an element that is relatively costly to deal with, they can be investigated with smaller efforts per particle and, thus, quite large systems sizes and accessible time-scales [31–33].

Other important topics are the effects of water on bulk and surface properties because the high reactivity of hydrogen induces local modification of the structure which can change the properties of the glass even at very low concentrations. The difficulty is then that fairly large systems must be investigated, which is the reason why relatively few simulations have been done on complex water-bearing glasses [9, 15]. At present, the main problem faced indeed remains the large computational effort required and hence more efficient methods are being devised to reduce the computing time. Examples are the so-called “order- N ” algorithms, with which the computational cost increases only linearly with the system size [34], or the second-generation Car–Parrinello approach [35]. Although these advances will make it possible to deal with much larger systems, including, for instance, 10^4 oxygen atoms, it is unlikely that they will allow to gain one more order of magnitude in system size. To study problems like the mechanical behavior of glasses on the mesoscale, simulations will thus have to be done with effective potentials. But even in these cases *ab initio* simulations will be very useful by providing more accurate potential parameters [36–38].

In most applications glass needs to be inert with respect to its environment. A particular glass is then selected for a given use on the basis of its physical properties. The range of glasses to be dealt in both industrial and natural contexts makes it necessary to pay attention to the strong dependences of physical properties on chemical composition, whose understanding is facilitated by the structural concepts presented in Section II. Because one produces most glasses by cooling melts, however, the fundamental issues to be discussed first are why vitrifiability varies so much with composition and how the glass transition varies with the cooling rate.

In the first chapter of this section both issues are discussed by M.J. Ojovan in the light of energetic, microscopic, and structural criteria (Chapter 3.1). Owing to the nonequilibrium nature of the glass transition, its thermodynamic treatment requires new concepts. From the notions of affinity and order parameter and simple relaxation models based on calorimetric measurements, insights are derived by J.-L. Garden and H. Guillou on the entropy irreversibly created at the glass transition and on processes such as physical aging below T_g (Chapter 3.2). Within the framework of irreversible thermodynamics, the issue of entropy at the glass transition is then examined by P. Gujrati who shows how both communal entropy and free volume vanish at an *ideal* glass transition where the viscosity divergence would take place (Chapter 3.3).

Following these theoretical accounts, three chapters consider specific physical properties. In the first, B. Hehlen and B. Rufflé deal with the various modes of vibrations existing in glasses, paying particular attention to the low temperatures at which the boson peak represents an excess of vibrational modes with respect to those predicted by the Debye model for crystals (Chapter 3.4). Of direct practical interest, the densities of glasses and melts and their temperature and pressure derivatives are then reviewed by M. Toplis who also presents empirical models predicting these properties as a function of chemical composition (Chapter 3.5). A similar approach is followed by P. Richet and D. de Ligny in the next chapter, which is mainly devoted to heat capacity and entropy from near 0 K to superliquidus temperatures: at lower temperatures, the properties of *glasses* are exclusively vibrational and mainly determined by the oxygen coordination of cations, whereas the picture is markedly more complicated above the glass transition by configurational contributions to the properties of *liquids*, whose nature remains largely elusive (Chapter 3.6).

After these overviews of key physical properties, the ground is ready for a thorough discussion of relaxation processes. Relying mainly on calorimetric measurements, U. Fotheringham describes how the concept of fictive temperature can be incorporated into various relaxation models to

predict accurately features of great practical interest such as thermal shrinkage and index of refraction changes as a function of time and temperature (Chapter 3.7). Because of extreme metastability, a special case of relaxation is that of glasses quenched at rates of the order of 10^6 K/min. As revealed by calorimetric experiments examined by Y. Yue, these *hyperquenched* glasses do show unusual features related to structural heterogeneities and to the existence of fragile-to-strong rheological transitions in glass-forming systems (Chapter 3.8).

The existence of polyamorphism, i.e. transitions from one amorphous phase to another, has recently been an unexpected discovery because the structure and properties of glasses were instead thought to vary continuously as a function of the quench temperature and pressure. As reviewed by P. McMillan and M. Wilding, these abrupt phase changes akin to first-order transitions in crystals have been extensively investigated and their origin accounted for in terms of the topology of configurational-energy landscapes (Chapter 3.9). Amorphous phases can also be prepared by high-pressure compression of crystals that undergo structural collapse when their elastic limits are exceeded. As explained again in terms of configurational-energy landscape by P. McMillan, D. Machon, and M. Wilding, the similarity of these phases with the dense polyamorphs formed at high pressures is not fortuitous (Chapter 3.10).

From the standpoint of mechanical stability, amorphous phases display a much greater variety of compression mechanisms than crystals, thanks to the lack of structural constraints imposed by the symmetry of a crystal lattice. In addition, the intrinsic strength of glasses should in principle be limited only by that of interatomic bonds since it is not reduced by grain boundaries. As explained by R. Hand, however, the actual strength is hundred times smaller because of the existence of surface flaws where the accumulation of stresses triggers breakage; whereas the abundance of flaws increases with time and their effects have to be treated statistically, their creation can be limited in various ways (Chapter 3.11). Strategies for strengthening glass are described in more detail by S. Karlsson and L. Wondraczek; in addition to elimination of flaws by mechanical polishing or flame finishing, these involve the creation of compressive stresses at the glass surfaces by either physical or chemical means, i.e. tempering by rapid, homogenous cooling (Figure 1) or exchange of smaller by bigger ions, e.g. replacement of Na^+ by K^+ (Chapter 3.12). Irradiation by energetic photons or subatomic particles is another source of defects reviewed by N. Ollier, S. Girard, and S. Peugeot who describe their effects on optical and mechanical properties and the ways in which these can be reduced (Chapter 3.13).

The last chapter is devoted to the special case of amorphous ices, which have recently received much attention not so much because of their cosmochemical importance, but because they are prime illustrations of polyamorphism. Their formation and properties are thus reviewed by R. Tournier who goes into the details of a thermodynamic model of nucleation and growth

originally designed for crystals – including numerical applications – to account for the formation of these amorphous ices and, in addition, to throw valuable light on the general problem of the glass transition in terms of transformations between supercooled liquids of different densities (Chapter 3.14).

3.1

Glass Formation

Michael I. Ojovan

Department of Materials, Imperial College London, London, UK

1 Introduction

Glasses can be formed by various methods, including physical vapor deposition, solid-state reactions, thermochemical and mechanochemical treatments, or liquid-state reactions with sol–gel techniques (Chapter 8.1). Amorphous solids can also be prepared under the action of high pressure (Chapter 3.10) or by irradiation of crystals (Chapter 3.13). In industry or in Nature (Chapters 7.1 and 7.2), however, vitrification most frequently relies on the extremely strong viscosity increases when melts are cooled until the glass transition eventually takes place before nucleation and crystal growth have developed (Chapter 5.4). The topic dealt with in this chapter will thus be glass formation by melt cooling.

In a first approximation, the glass transition is conveniently characterized by a single parameter, the glass transition temperature T_g (Chapter 3.2). Under typical cooling rates of the order of 10 K/s, the standard T_g is the temperature at which the viscosity is about 10^{12} Pa.s (10^{13} P) at the macroscopic observational timescales of 10^2 – 10^3 seconds that are relevant to actual glass formation. As defined in this way, T_g is always significantly lower than the melting (or liquidus) temperature T_m . It can be roughly estimated with the Kauzmann formula $T_g \approx 2T_m/3$ [1].

In principle, any liquid vitrifies if the melt is cooled sufficiently fast to prevent crystallization from happening. This is by definition the case of the vast bulk of

commercially used glasses, which are made up of oxides. In glass technology, SiO_2 , GeO_2 , B_2O_3 , and P_2O_5 are archetypal *glass formers* in that they easily form glass networks by themselves or in combination with other oxides. But in practice it is not obvious to predict which materials readily vitrify and under what conditions they do so. As a matter of fact, the high viscosities that favor vitrification are related to structural factors whereas configurational complexity also contributes to frustrate crystallization. Here, particular attention will thus be paid not only to the kinetics of vitrification and its theoretical aspects but also to these factors.

In preamble, however, it is useful to examine the way in which glass is defined because of the possibly surprising fact that there is no generally accepted definition of this state of matter. Likewise, a few fundamental points will be summarized about relaxation, the process by which the structure and properties of an amorphous substance tend to reach their equilibrium values to vanish below the glass transition (Chapter 3.7).

2 Glass and Relaxation

According to the International Commission on Glass (ICG, Chapter 9.11), a glass is a homogeneous amorphous solid material produced when a viscous molten material is cooled rapidly enough through the glass transition range without leaving sufficient time for the formation of a regular crystal lattice. As for the International Union of Pure and Applied Chemistry (IUPAC), its Compendium of Chemical Terminology puts instead the emphasis on the process through which a glass is produced by defining it as a second-order transition taking place upon cooling of a supercooled melt [2]. Additionally, IUPAC states that below T_g the physical properties of glasses vary in a manner like those of crystalline phases.

Of more serious consequences that this divergence is the fact that the nature of the glass transition is not yet well understood in spite of its fundamental importance (Chapter 3.3). One reason is the almost undetectable structural differences noted between the supercooled liquid and glass phases, which contrast with the marked changes observed in mechanical and other physical properties associated with the extremely large changes in the timescale of relaxation processes at T_g and below.

Specifically, a glass has a topologically disordered distribution of atoms or molecules, like a liquid, but it has also the elastic properties of an isotropic solid. Moreover, the translation-rotation symmetry at T_g is unchanged as the glass retains the topological disorder of the fluid from which it formed. This symmetry similarity of both liquid and glassy phases generally leaves unexplained the basic differences observed between their properties. An exception is the qualitative difference that has been demonstrated in the symmetries of liquid and glasses in terms of Hausdorff dimensionality for the system of bonds which shows a stepwise change exactly at T_g [3]. The reason is that broken bonds in glasses are present as point defects, thus forming a set of zero-Hausdorff dimensionality, whereas in liquids just above the T_g they are associated in macroscopic percolating clusters that form sets characterized by the Hausdorff dimensionality ≈ 2.5 [3].

Although glasses are metastable materials with respect to isochemical crystals, their transformation to a thermodynamically stable crystalline structure is kinetically impeded. The metastability of silicate glasses commonly produced industrially is not a practical concern as most of them are stable for times much longer than any imaginable timescales of use. In practice, that there is no stress relaxation at room temperatures is indicated by the fact that high permanent internal stresses are preserved in glass articles made more than several millennia ago, and even in billion-year-old extraterrestrial glasses (Chapter 7.1).

The reason for this stability is that relaxation processes are controlled by viscosity. The characteristic time τ required to achieve time-independent parameters can be derived from Maxwell's simple relaxation model, which predicts that $\tau = \eta/G$, where G is the shear modulus and η the viscosity (Chapter 3.7). The higher the viscosity, the longer the relaxation time. Besides, viscosity changes are thermally activated. Glass-forming oxides are characterized by high activation energies and very high viscosities under normal conditions. As an extreme example, fused silica has an activation energy for viscous flow of Q_H of 759 kJ/mol at lower temperatures and a shear modulus of about 31 GPa, which implies relaxation times τ_M as long as 10^{98} years at room temperature, an immeasurably longer time than even the $14 \cdot 10^9$ years lifetime of the universe.

3 Kinetic Theory of Vitrification

As already stated, vitrification on cooling is tantamount to bypassing crystallization, which would bring the material to an ordered state of matter of lower energy and, thus, of greater stability. If cooled quickly enough, virtually any material can vitrify. Hence, an important question is to know how fast the melt should be cooled to avoid detectable crystallization. Actually, the cooling rates of good glass formers range from 1 to 10 K/s and those of poor ones are higher than ~ 100 K/s. Familiar glass-forming materials such as SiO_2 -rich silicates thus do not require fast cooling. An extreme example is supercooled $\text{NaAlSi}_3\text{O}_8$, which did not crystallize at all after five years spent 90 K below the melting point of the albite feldspar mineral [4]. Even though the quenching rate of a liquid medium can be increased to about 10^3 K/s, such high values may not be fast enough to avoid partial or complete crystallization. In silicates, SiO_2 -poor olivine compositions (e.g. Mg_2SiO_4) are notorious examples of liquids that are difficult to vitrify at such rates [5]. Quickly crystallizing liquids such as metals may require still faster cooling. For instance, early metallic glasses (Chapter 7.10) had to be splat quenched in the form of thin ribbons at about 10^6 K/s to avoid crystallization, mainly because their viscosities remain very low with decreasing temperatures (Figure 1).

An added complication is that melts can be good glass formers only within limited composition regions as indicated in Figure 2 for aluminosilicates. Compilations of glass-forming regions of phase diagrams are available [6–8]. As a rule, however, glass formation is enhanced in more complex systems. Oxide systems containing a variety of cations are easier to obtain in a glassy state as their liquidus temperature is lower and their complexity

Figure 1 Critical cooling rates for glass formation. Reduced glass transition temperature T_g defined as T_g/T_m , where T_m is the liquidus temperature.

Figure 2 Glass formation ranges in aluminosilicate systems (shaded areas). *Source:* After [6], courtesy P. Richet.

necessitates longer times for diffusion-controlled redistribution of their diverse constituents before crystal nucleation and growth can take place.

If crystallization is bypassed, the melt undergoes the glass transition in a temperature range that shifts to higher temperatures for higher cooling rates. Both the width of this range and the value of T_g within it may vary by typically several tens of degrees. As the width and variation are small compared with T_g , it is therefore possible to manage a cooling schedule rapid enough to keep the degree of crystallization negligible. Volume fractions considered to be negligible are lower than 1 ppm, which is the typical instrumental limit for detecting the presence of crystals by microanalytical techniques (Chapter 2.3).

If ν designates the volume fraction of crystalline(s) phase(s), the material is amorphous if $\nu = 0$, crystalline if $\nu = 1$, and polyphase or heterogeneous when $0 < \nu < 1$. Under isothermal conditions the volume fraction of a growing crystalline phase varies with time as described by the Johnson–Mehl–Avrami–Kolmogorov equation (see [9] for references and details):

$$\nu = 1 - \exp \left[-\frac{\pi}{3} I_\nu u^3 t^4 \right], \quad (1)$$

where u is the rate of crystal growth and I_ν the nucleation rate.

If both rates can be estimated, the volume fraction of the crystalline phase ν achieved for a given cooling rate can be calculated and the results be compared with experimental data. The rate of homogeneous nucleation is given by James equation:

$$I_\nu = \frac{n_\nu k_B T}{3\pi\lambda^3 \eta} \exp \left[-\frac{W^*}{k_B T} \right]. \quad (2)$$

Here W^* is the thermodynamic barrier to homogeneous nucleation, n_ν the number of molecules or formula units of nucleating phase per unit volume, λ a jump distance, and η viscosity. For heterogeneous nucleation, the thermodynamic barrier to nucleation actually becomes $W_{h*} = W^*(2 + \cos\theta)(1 - \cos\theta)^2/4$, where θ is the contact angle between the crystal and the nucleating heterogeneity. The rate of crystal growth is given by Wilson–Frenkel equation:

$$u = \frac{fD_c}{\lambda} \left[1 - \exp \left[-\frac{\Delta G_\nu V_m}{RT} \right] \right], \quad (3)$$

where f is the interface site factor, D_c the kinetic (diffusion) coefficient, V_m the molar volume, and ΔG_ν the difference in Gibbs free energy between unit volumes of the crystal and liquid.

One then obtains the critical cooling time (t_c) and rate (q_c), for a defined volume fraction of crystals ν_c . Taking the aforementioned value ν_c of 1 ppm, one obtains

Figure 3 Determination of the critical cooling rate from a time temperature transformation diagram.

$$t_c = \left(\frac{3\nu_c}{\pi I_\nu u^3} \right)^{1/4} \quad (4a)$$

and

$$q_c = \frac{(T_m - T_g)}{t_c} \approx \frac{T_m}{3t_c}. \quad (4b)$$

Despite its general correctness and qualitative agreement with experiments, the kinetic theory suffers from limited quantitative applications. Whereas quantitative agreement has been achieved for simple silicate systems, the discrepancy is of many orders of magnitude in most cases [6, 8].

In practice, the critical cooling rate (CCR) is determined from the so-called time temperature transformation (TTT) diagrams, which represent nose-shaped curves with a constant crystal fraction on time–temperature axes (Figure 3). To ensure the obtention of a glass with a crystal volume fraction lower than ν , it is required to follow a cooling pathway such that the cooling line (curve) will not touch the nose [10]. The CCR is then found as follows:

$$q_c = \frac{(T_m - T_n)}{t_n}. \quad (5)$$

Examples are listed in Table 1.

4 The Viscosity Factor

The definition of the glass transition in terms of the standard glass transition derived from the viscosity–temperature relationship, $\eta(T)$, is not thermodynamic, but operational [8]. As determined from changes in second-order derivatives of thermodynamic variables, the glass transition takes place at viscosities in the range 10^8 – 10^{13} Pa s depending on the cooling rate. In view of

Table 1 Critical cooling rate for some glasses, K/s.

Material	Nucleation mechanism			
	Homogeneous	Heterogeneous $\theta = 100^\circ$	Heterogeneous $\theta = 60^\circ$	Heterogeneous $\theta = 40^\circ$
SiO ₂	9×10^{-6}	10^{-5}	8×10^{-3}	2×10^{-1}
GeO ₂	3×10^{-3}	3×10^{-3}	1	20
Na ₂ O 2 SiO ₂	6×10^{-3}	8×10^{-3}	10	3×10^2

Water	10^7			
Ag	10^{10}			

Source: After [9].

the very steep temperature dependence of viscosity, a great difference in this parameter results in only small variations of the operational T_g .

As has long been recognized, glass formation is therefore easier in eutectic regions because freezing-point depressions enable lower temperatures and higher viscosities to be reached [11]. However, viscosity at the liquidus is not a single scaling parameter for assessing glass-forming ability. The temperature dependence of the viscosity below T_m must also be considered because vitrification takes place much below the liquidus [6, 8].

Viscous flow in glass-forming liquids is characterized by deviations from Arrhenius laws with an activation energy Q that decreases from a high Q_H near the glass transition to a low Q_L at superliquidus temperatures. As a fragility index characterizing the temperature dependence of viscosity, Doremus [12] has proposed the ratio:

$$R_D = \frac{Q_H}{Q_L}. \quad (6)$$

Short (or fragile) and long (or strong) glass melts are, therefore, characterized by R_D values higher and lower than 2, respectively.

Many equations have been proposed to express viscosity–temperature relationships (Chapter 4.1, [13–15]). Consistent with Doremus criterion, an exponential expression with activation energies Q_L and Q_H at low and high temperatures, respectively, [13] will be used here because it results from the configuron percolation theory (CPT), which accounts for viscous flow in terms of elementary excitations resulting from broken bonds named *configurons* [14, 16]. This equation (Sheffield model) is

$$\eta(T) = A_1 T \left[1 + A_2 \exp\left(\frac{B}{RT}\right) \right] \left[1 + C \exp\left(\frac{D}{RT}\right) \right], \quad (7)$$

where $A_1 = k/6\pi r D_0$, $A_2 = \exp(-S_m/R)$, $B = H_m$, $C = \exp(-S_d/R)$ and $D = H_d$, R the gas constant, k Boltzmann

constant, r the configuron radius $D_0 = fg\lambda^2 zp_0\nu_0$, f the correlation factor, g a geometrical factor ($\sim 1/6$), λ the average jump length, ν_0 the configuron vibrational frequency or the frequency (with which the configuron attempts to surmount the energy barrier to jump into a neighboring site), z the number of nearest neighbors, p_0 a configuration factor, H_d the enthalpy, S_d the entropy of formation, and H_m and S_m the enthalpy and entropy of motion of the configurons.

In practice, one finds that $A_2 \exp(B/RT) \gg 1$, i.e. that four parameters usually suffice for Eq. (7) to be fitted to practically all available experimental viscosity data [17]. Comparison with other viscosity models and numerical calculations have confirmed the excellent description of the viscosity provided by Eq. (7) for simple and complex organic and inorganic compositions (e.g. [13]). This equation can be readily approximated within narrow temperature intervals by expressions derived from the well-known Vogel-Tammann-Fulcher, Adam–Gibbs, Avramov–Milchev, or Sanditov models [14, 15, 17]. It can be used at all temperatures and gives the correct Arrhenius-type asymptotes at high and low temperatures, namely $\eta(T) \sim \exp(Q_H/RT)$ at $T \ll T_g$, and $\eta(T) \sim \exp(Q_L/RT)$ at $T \gg T_g$, where $Q_H = H_d + H_m$ and $Q_L = H_m$. Obviously, the activation energy of viscosity reduces to a low value equal to H_m at high temperatures when temperature fluctuations create plenty of configurons. In contrast, some bonds need to be broken in the glassy state as temperature fluctuations do not create them effectively so that the activation energy then takes its full value $Q_H = H_d + H_m$.

5 Structural Factors

Apart from inhomogeneities and potential phase separation, glasses lack long-range order but do possess short- and medium-range ordering (Chapter 2.1). A number of models have aimed at revealing the most characteristic

structural aspects of good glass formers. The most noted structural criterion for ready glass formation, i.e. at rates q_c lower than 10 K/s, is based on Zachariasen theory in which the oxide glasses A_mO_n are assumed to be 3-D networks obeying four rules: (i) the oxygen is linked to two atoms of A; (ii) the oxygen coordination number around A is three or four; (iii) the cation polyhedra share corners; and (iv) at least three corners are shared [18]. This theory is referred to as crystallochemical, but was applicable only to oxide glasses in its original form; it led to the so-called 3-D continuous random network (CRN) model (Chapter 2.1). With respect to a glass and its isochemical crystal, the basic postulates of CRN are that: (i) interatomic forces are similar in both phases; (ii) the glass is in a slightly higher energy state; (iii) nearest-neighbor coordination polyhedra are similar; and (iv) the nature of interatomic bonds is also similar.

The strong points of Zachariasen's model are that it predicts the existence of the main oxide glass formers (SiO_2 , GeO_2 , B_2O_3 , P_2O_5 , etc.) and glass modifiers (Na_2O , CaO , etc.) and makes room for the distinction between bridging (BO) and non-bridging oxygens (NBO). Its main limitation is that it does not consider at all modified oxides or multicomponent systems, or even non-oxide glasses. In addition, several exceptions to its rules are found as exemplified by alumina-lime glasses and chain-like glass structures (e.g. metaphosphate glasses).

Smekal [19] thus developed the concept of the mixing bond nature of (good) glass formers. He noted that pure covalent bonds are incompatible with a random arrangement in view of sharply defined bond lengths and angles. Purely ionic or metallic bonds lack any directional characteristics so that the presence of *mixed* chemical bonding is necessary for glass formation. Indeed, known glass formers obey this concept: (i) inorganic compounds like SiO_2 or B_2O_3 where the A–O bonds are partly covalent and partly ionic; (ii) elements (S, Se) having chain structures with covalent bonds within the chain and van der Waal's forces between them (Chapter 6.5); and (iii) organic compounds containing large molecules with covalent internal bonds and van der Waals' forces between the molecules (Chapter 8.8).

Alternatively, Stanworth proposed a criterion for glass formation according to which the electronegativity of cations in oxide glasses falls within a certain range between 1.90 and 2.20 [20]. Although the electronegativity values of the constituent atoms can be used to predict the formation of many glasses, this criterion cannot account for systems when bond strength needs to be considered as a secondary criterion.

Sun developed the bond-strength model on the assumption that, when a melt vitrifies, the stronger the metal–oxygen bond, the more difficult the structural

rearrangements necessary for crystallization become and, hence, the easier is glass formation. Glass formation is then ensured by the connectivity of bridging bonds combined with strong bonding between atoms (ions) [21]. Sun thus classified oxides according to their bond strengths so that glass formers form strong bonds with oxygen to yield a rigid network, which results in a high viscosity. He defined modifiers as weakly bonding with oxygen in such a way that they disrupt and modify the network. Without producing glasses on their own, they do form intermediate bonds with oxygen and thus aid vitrification with other oxides.

In practical terms, Sun's energy criterion establishes a correlation between the glass-forming tendency and the strength of the bond between the elements and the anion in the glass. The single bond strength E_b was defined as:

$$E_b = \frac{E_d}{CN}, \quad (8)$$

where CN is the coordination number and E_d the dissociation energy of oxides into their gaseous elements. For B_2O_3 , SiO_2 , GeO_2 , P_2O_5 , or Al_2O_3 , the single bond strength of network formers with oxygen is higher than 330 kJ/mol. Values lower than 250 kJ/mol hold for network modifiers such as Li, Na, K, Mg, or Ca whereas intermediate cations such as Ti, Zn, and Pb are characterized by values intermediate between these two figures.

For both Zachariasen and Sun models Al^{+3} is a challenge. Although Al_2O_3 satisfies Zachariasen's criteria, it does not form a glass. Likewise, with $E_d = 1320$ – 1680 kJ, alumina should be a glass former at a CN of 4 for Al^{3+} and a modifier at a CN of 6. Sun model was also specific to oxides. It did not account for chalcogenide glasses (Chapter 6.5) with typical bond strength of 170 kJ/mol along the chains (covalent bond) and less between the chains (van der Waals forces). An interesting intermediate class of oxide is formed by TeO_2 , MoO_3 , Bi_2O_3 , Al_2O_3 , Ga_2O_3 , and V_2O_5 , which do not vitrify by themselves but will do so when mixed with other (modifier) oxides.

Rawson modified Sun's criteria for glass formation [22] by considering the ratio of the bond strength and energy available at the melting point T_m instead of the coordination number. He noted that glass formation then correlates better with E_b/T_m , being achieved for values of this ratio higher than 0.05 kJ/mol K. The higher this value, the lower the probability for bonds to be broken at T_m , and hence the greater the vitrifiability. Glass formation is thus easier for high bond strength and low melting (liquidus) temperature, which implies that eutectic compositions do favor it.

Based on Rawson and Sun approaches, a modified glass-forming criterion termed the *Thermodynamic Relative Glass-Forming Ability* has recently been proposed in terms of the parameter $E_b/C_p T_m$, where C_p is the isobaric

heat capacity [23], which can be regarded as an extension of Rawson's criteria. The ordering that results from this model is not convincing, however, and its basic ideas remain to be well justified.

Dietzel [24] characterized the ability of cations to enter the network structure by their field strength, which he defined as

$$F = \frac{Z}{r^2}, \quad (9)$$

where Z is its valence and r its ionic radius ($\text{\AA}$) in the oxide. As listed in Table 2, lower field-strength cations (e.g. alkalis) are network modifiers, whereas ions with higher field strengths (such as Si, P, or B) are network formers. Interestingly, Dietzel model is appropriate for describing phase separation, either through crystallization or unmixing, in cooled binary systems such as $\text{SiO}_2\text{--P}_2\text{O}_5$, $\text{SiO}_2\text{--B}_2\text{O}_3$, or $\text{B}_2\text{O}_3\text{--P}_2\text{O}_5$. This may generally be the case when the field strengths of two cations are approximately equal since forming a single stable crystalline compound normally requires a difference ΔF greater than 0.3. The number of possible stable compounds increases with ΔF as well as the tendency to form glass. For a binary system, glass formation is likely for Δf larger than 1.33 although this theory is useful to categorize the glass-forming ability of conventional systems, but not universally [25].

Finally, the topological constraints theory introduced by Phillips [26] must also be mentioned. As reviewed in Chapter 2.7, it indicates that the glass-forming tendency is maximized when the number of constraints is equal to the number of degrees of freedom in the structure.

In summary, vitrification is favored by high viscosity and configurational complexity. A more complicated chemical composition translates into a greater number of compounds that could nucleate. Owing to mutual competition between these possible crystals, nucleation and growth crystals end up being frustrated. That they do not take place upon rapid cooling thus is a consequence of a *confusion principle* [8].

6 Glass-Liquid Transition

Structural theories with energetic and microstructural criteria such as topological constraints describe elements that favor glass formation, i.e. the preservation of a topologically disordered distribution of basic elements in glasses. Kinetic theory shows how to avoid crystallization rather than explaining why the vitreous state really forms through the liquid–glass transition – it is at T_g that the “drama” occurs! Although kinetically controlled, the glass transition manifests itself as a second-order phase

transformation in the sense of Ehrenfest classification. Depending on the kind of measurement performed, it is thus revealed either as a continuous change of first-order thermodynamic properties such as volume, enthalpy, entropy, or as a discontinuous variation of second-order thermodynamic properties such as heat capacity or thermal expansion coefficient across the glass transition range.

As indicated by its name, the CPT treats the glass transition as a percolation-type second-order transformation [27]. It pictures it as the disappearance in the glassy state of percolating clusters of broken bonds – configurons. Above T_g , percolating clusters, which are formed by broken bonds, enable a floppier structure and hence a greater degree of freedom for atomic motion so that it results in a higher heat capacity and thermal expansion coefficient. Below T_g there are no extended clusters of broken bonds such that the material has acquired a 3-D structure with a bonding system similar to that of crystals except for lattice disorder. This disordered lattice then contains only point defects in the form of configurons. Agglomerates of fractal structures made of these broken bonds are present only above T_g , which is given by:

$$T_g = \frac{H_d}{S_d + R \ln [(1 - \phi_c)/\phi_c]}. \quad (10)$$

In this equation H_d and S_d are the quasi-equilibrium (isostructural) enthalpy and entropy of configurons present in Eq. (7) and ϕ_c is the percolation threshold, i.e. the critical fraction of space occupied by spheres of bond-length diameters located within the bonding sites of the disordered lattice.

For strong melts such as SiO_2 , the percolation threshold in Eq. (10) is given by the theoretical (universal) Scher–Zallen critical density ϕ_c of 0.15 ± 0.01 , which results in a practical coincidence between the calculated and measured T_g values. The parameter H_m has no influence on T_g as it characterizes the mobility of atoms or molecules through the high-temperature fluidity of the melt – see Eq. (7). Because H_d is half of bond strength (Table 2), Eq. (10) shows that the higher this strength, the higher T_g . The vacancy model of the generalized lattice theory of associated solutions provides direct means to calculate thermodynamic properties as well as the relative number of bonds formed in glasses and melts when the second coordination sphere of atoms is taken into consideration [28].

In terms of chemical bonds, an amorphous material transforms to a glass on cooling when the topology of connections changes (Table 3), i.e. when the Hausdorff dimensionality of broken bonds changes from the 2.5 value of a fractal percolating cluster made of broken bonds to the zero value of a 3-D solid. In terms of bonding lattice, the

transition from the glass to the liquid upon heating may be explained as a reduction of the topological signature (i.e. Hausdorff dimensionality [29]) of the disordered bonding lattice from 3 for a glass (3-D bonded material) to the fractal D_f of 2.4–2.8 of the melt. These are the main changes that account for the drastic variations in material properties at glass-to-liquid transition [27].

Most experimental T_g data have been obtained by differential thermal analysis (DTA), differential scanning calorimetry (DSC), or dilatometry [30], where T_g is generally defined as the temperature at which the tangents to the glass and liquid curves of the relevant property intersect (Chapter 3.2). Heating (cooling) rates for DTA/DSC measurements are typically as high as 10 K/min whereas they are in 3–5 K/min range in dilatometry. As already stated, the glass transition is not abrupt but typically occurs over a few tens of degrees. For not very high cooling rates (q), its dependence on q is given by the Bartenev–Ritland equation:

$$\frac{1}{T_g} = a_1 - a_2 \ln q, \quad (11)$$

where a_1 and a_2 are empirical constants. Although Eq. (11) also results from CPT, it should be replaced by a generalized version at high cooling rates [31]. In addition, CPT predicts that the transition takes place not as a sharp discontinuity, but over a finite temperature

interval where the properties of the material depend on time as well as on thermal history.

Following the analysis of [8], we may ask why viscous liquids eventually vitrify instead of remaining in the supercooled liquid state when they escape crystallization. One answer to this question is purely kinetic and relies only on increasingly long relaxation times or increasing viscosities on cooling. The glass transition would result only from the limited timescale of feasible measurements so that any glass would eventually relax to the equilibrium state if experiments could last forever. In fact, a simple thermodynamic argument proposed by Kauzmann [32] indicates that this answer is incorrect. The reason originates in the existence of a configurational contribution that causes the heat capacity of a liquid to be generally higher than that of a crystal of the same composition. As a consequence, the entropy of the liquid decreases on cooling faster than that of the crystal (Figure 4).

If the entropy of the supercooled liquid were extrapolated to temperatures much below T_g , it would become lower at a temperature T_K than that of the crystal. Because it is unlikely that an amorphous phase could ever have a lower entropy than an isochemical crystal, the conclusion known as Kauzmann's paradox is that an amorphous phase cannot exist below T_K . The temperature of such an entropy catastrophe constitutes the lower bound to the metastability limit of the supercooled liquid. As internal equilibrium cannot be reached below T_K , the liquid must undergo a phase transition before reaching this temperature. This is, of course, the glass transition, and Kauzmann's paradox suggests that, although it is kinetic in nature, it anticipates a thermodynamic transition. In other words, CPT treats the glass transition as

a true phase transformation although as a nonequilibrium one. The liquid transforms in a continuous way into a glass, which behaves mechanically as a crystalline solid when the motions of atoms become very much frustrated below T_g where the extensive clusters of broken bonds of the liquid are no longer present. The degree of frustration then is actually the same as in a 3-D crystalline material so that the heat capacity does not show the same high rate of change as in the liquid. This feature is clearly seen both in experiments and as an outcome of the CPT concept (Figure 5). Importantly, CPT yields a universal law for

Figure 4 Entropy of the amorphous and crystalline phases of diopside, $\text{CaMgSi}_2\text{O}_6$. Source: After [8]. The liquid transforms into a glass below T_g , therefore the entropy of condensed phase (upper curve) does not follow the dashed line which is an extension of liquid entropy curve below T_g .

susceptibilities such as heat capacity or thermal expansion near T_g [3, 27]:

$$C_p, \alpha \propto \frac{1}{|T - T_g|^{0.59}}. \quad (12)$$

A last feature deserving to be mentioned is the “universal” dependence of the light scattering intensity on the time after a temperature jump in the glass transition range of oxide glasses, which is known as the Bokov effect [33]. The intensity displays a maximum whose height and location on the timescale depends on the previous history of the glass. The Bokov effect is associated with nonequilibrium fluctuations produced by coupling between hydrodynamic modes. Detailed investigations in the past decade have demonstrated that similarities observed in the glass transition region of oxides and polymers account for structural transformations related to the formation of spatially extensive structures, which in turn could be related to clustering effects similar to that envisaged by CPT and other similar models. The Bokov effect thus is providing additional arguments to characterize the glass transition as a second order like phase transformation rather than simply as a slowing down of dynamic processes.

7 Perspectives

Understanding vitrification mechanisms is of great importance either practically or theoretically. Although progress made in this respect has been very impressive, many of the questions remain unresolved. Among them, a central one is that of the glass transition itself, which has a pronounced relaxational, kinetic character in spite of its similarity with a second-order phase transition in the Ehrenfest sense with volume and entropy continuity, but discontinuities of their derivatives that are used in practice to detect T_g . Discussion about the nature of glass continues. After some lull it has gathered new momentum, especially in the second decade of the new century as the microscopic mechanisms generating the glassy state of matter are still debated. Future developments could be based on computer modeling that does also show the appearance of discontinuities in derivative thermodynamic parameters at the glass transition.

Thermodynamics of Glasses

Jean-Luc Garden and Hervé Guillo

CNRS, Institut Néel and Université de Grenoble Alpes, Grenoble, France

1 Introduction

Thermodynamics states that the properties of a system in equilibrium depend neither on time nor on past history. Glasses clearly violate this postulate. Not only do their properties depend on history but they also vary with time at temperatures at which relaxation toward internal thermodynamic equilibrium does occur, but at a rate slow enough to be observable at the timescale of the experiment performed. To deal with glasses, thermodynamics must thus consider nonequilibrium states and their actual cause, namely the irreversibility of the transition that occurs when relaxation times eventually become much longer than experimental timescales such that the material freezes in as a glass.

Much attention is currently paid to the processes driving the glass transition at a microscopic scale and also to their implications for the macroscopic properties of glasses. Because this topic is extensively discussed in this chapter, we will deal here with a second fundamental issue, namely that of the phenomenological approaches followed to understand the observable macroscopic properties of glasses and, thus, to design new applications. To quote a single example, density gradients in tempered glasses are the key to thermal strengthening, which is achieved irreversibly upon cooling (Chapter 3.12).

In this chapter, the basic concepts of macroscopic nonequilibrium thermodynamics will first be summarized and illustrated with experimental heat capacities for a model system, PolyVinylAcetate [PVAc, $(C_4H_6O_2)_n$]. The basic concepts of equilibrium and nonequilibrium will then be introduced to point out why glasses challenge

the laws of thermodynamics. Next, properties of the supercooled liquid state above T_g will be presented and the phenomenology of the glass transition examined in the light of calorimetric data, in particular in terms of configurational properties. The basics of nonequilibrium thermodynamics in the glass transition range will finally be reviewed along with the issue of aging below the glass transition range.

2 Basics of Nonequilibrium Thermodynamics

In thermodynamics one investigates the changes occurring when a system passes from a state A to another state B. At constant chemical composition, the system is in *internal* equilibrium if its state is defined by only two macroscopic variables such as temperature (T), pressure (P), volume (V), enthalpy (H), internal energy (U), or Gibbs free energy (G). Their values are not only constant but independent of the pathway actually followed between any two states A and B. As stated by the First Law of thermodynamics, between A and B the internal energy varies as:

$$\Delta U_{A \rightarrow B} = Q_{A \rightarrow B} + W_{A \rightarrow B}, \quad (1)$$

where $Q_{A \rightarrow B}$ and $W_{A \rightarrow B}$ are the heat and work exchanged by the system with its surroundings, respectively. Likewise, the entropy is decomposed into two parts,

$$\Delta S_{A \rightarrow B} = \frac{Q_{A \rightarrow B}}{T} + \Delta_i S_{A \rightarrow B}, \quad (2)$$

where the first represents the heat exchanged with the surroundings and the second the entropy created within the system itself during the transformation.

Reviewers: M.A. Ramos, Laboratorio de Bajas Temperaturas, Universidad Autónoma de Madrid, Spain
A. Saiter, Physics of Materials Group, University of Rouen, Saint-Etienne du Rouvray cedex, France

If two equilibrium states are connected by a reversible process, then $\Delta_i S_{A \rightarrow B} = 0$. If the system undergoes instead an irreversible process through which it falls out of equilibrium, then $\Delta_i S_{A \rightarrow B} > 0$ since a spontaneous process is always associated with an entropy increase of the system. Upon glass formation by cooling, pressure increase, or other means, the equilibrium liquid is continuously losing internal equilibrium. As will be discussed here, the question arises as to whether there is any finite production of entropy and – if so – whether this quantity is of importance regarding the other terms involved in the process.

The Third Law of thermodynamics postulates that the entropy of a perfectly ordered system is zero at 0 K. In contradiction with it, however, calorimetric measurements indicate that glasses not only possess nonzero entropies at 0 K but that this *residual entropy* depends on thermal history as illustrated by a simple entropy cycle calculated from measured heat-capacities and entropy of fusion (ΔS_f). Beginning with a perfectly ordered crystal, whose entropy thus is 0 at 0 K, one derives the entropy of the crystal at its congruent temperature of fusion T_f , then that of the melt from this temperature down to the glass transition, and finally that of the glass down to 0 K (Figure 1). The difference S_0 between this entropy and that of the crystal at 0 K is the residual entropy (Table 2), which increases with higher glass transition temperatures and, thus, with higher cooling rates, reflecting the increasingly wide distribution of configurational states obtaining with increasing temperatures.

A finite residual entropy at 0 K might seem to contradict the Third Law of thermodynamics. As justified by Jones and Simon [1], however, there is no contradiction because this law applies only to crystals and other systems in internal equilibrium, which are necessarily ordered at 0 K to minimize their Gibbs free energies. This is not the case of glasses, which do obey the Nernst theorem [2] since they cannot pass from one entropy state to another at 0 K ($\Delta S = 0$ for two neighboring glassy states at 0 K).

Although such determinations also made for partially disordered crystals like ice I_h or CO have long been

explained by simple statistical mechanical models, the very concept of residual entropy has recently been debated [3]. On the assumption that ergodicity must hold for the entropy to be defined, the proponents of a *kinetic* view have claimed that the configurational entropy undergoes an abrupt jump at the glass transition in order to reach the zero value of the crystal entropy at 0 K. In contrast, the proponents of the *conventional* view have stressed that what matters is not time averages but spatial averages of configurational microstates [3], which is the reason why the measured residual entropies do make sense physically and correlate with the specific structural features of glasses and disordered crystals.

By definition, equilibrium thermodynamics cannot alone account for fundamental questions raised when relaxation is too slow with respect to experimental time-scales. Owing to the kinetic nature of the problem, use has been made of the formalism originally developed for the kinetics of chemical reactions by De Donder and his school [4]. With values increasing as the reaction proceeds, a new variable, the advancement of reaction, $\xi(t)$ is defined to characterize the state of the system as a function of time, t , such that the reaction rate is simply $d\xi(t)/dt$. This extensive variable, expressed in mol, accounts for the distribution of matter (local mass or density variation), or the molecular structure, within the system at any time. A new state function, the affinity, A , is then introduced to relate $\xi(t)$ to the driving force of the reaction, its Gibbs free energy (at constant T and P):

$$A(P(t), T(t), \xi(t)) = \left(\frac{-\partial G}{\partial \xi} \right)_{P,T}. \quad (3)$$

The affinity A , expressed in J/mol, is the intensive conjugate variable of ξ . All time dependences are thus embedded into the time variations of the internal parameter ξ , or A , and of the other variables that are controlled experimentally (e.g. T , P).

For a relaxing system, the instantaneous entropy production was simply written by De Donder as the product of the thermodynamic force and the corresponding flux [4],

Figure 1 Entropies of the crystal, liquid, supercooled liquid and glass phases of a substance.

Table 1 Thermodynamic states in terms of affinity and its derivatives and in terms of rate of advancement of the process.

Rate of advancement $d\xi/dt$ (extensive, mol/s) Affinity A (intensive, J/mol)	$d\xi/dt = 0$	$d\xi/dt \neq 0$
$A = 0$ and $dA = 0$	True equilibrium; liquid state; $\sigma_i = 0$	Unphysical
$A = 0$ and $dA \neq 0$	Isomassic state; $\sigma_i = 0$	False equilibrium; nonequilibrium state; $\sigma_i = 0$
$A \neq 0$ and $dA = 0$	Isomassic, isoaffine state; $\sigma_i = 0$	Isoaffine state; $\sigma_i \neq 0$
$A \neq 0$ and $dA \neq 0$	Nonequilibrium; glassy state; $\sigma_i = 0$	Nonequilibrium; viscous state; $\sigma_i \neq 0$

Liquid, glass, and relaxing liquid states are indicated by gray cells. The other cells indicate particular states that can be encountered or not during the glass transition. The value of the rate of production of entropy is indicated in each cell.

$$\sigma_i = \frac{d_i S}{dt} = \frac{A}{T} \times \frac{d\xi}{dt}, \quad (4)$$

where the thermodynamic force actually is A/T , for the sake of dimensional analysis (the entropy production being in W/K).

Regarding the glass transition, the problem boils down to know A and ξ (or $d\xi/dt$) and how they evolve with time. Depending on the values of both parameters, however, at this point several cases must be distinguished because not all of them are relevant (Table 1). The first and simplest case is that for which both A and $d\xi/dt$ are zero. It is that of the equilibrium liquid, which will thus be first considered in its metastable, supercooled extension.

3 Supercooled Liquids

Although the liquid state is generally far from simple, it can be considered as an equilibrium reference at viscosities (η) low enough that flow is easy, i.e. at high-enough temperatures at the pressure considered. In that case, the diffusion of microscopic entities, be they molecules or atoms, obeys the Stokes-Einstein relation, which relates the diffusivity D to the temperature and viscosity with:

$$D = \frac{k_B T}{C\eta}, \quad (5)$$

where the coefficient C is a geometrical factor fixed by the boundary condition of the flow.

From its position at time t_0 , a diffusing entity travels a kind of random walk over an average distance $d \sim \sqrt{D(t-t_0)}$ as a function of time. For low-viscosity liquids and high temperatures, D is high so that entities explore a great many different positions and configurations in a time shorter than that needed to perform a physical measurement. They do it through degrees of freedom that include not only thermal motions of translation,

rotation, and vibration but also the complex kinds of atomic motions collectively termed *configurational*, which are governed by strong short-range repulsions and long-range attractions in molecular liquids. The measurement then averages out all these configurations.

Picturing these motions at a microscopic scale is difficult, however, especially for complex liquids or melts with various interacting entities. In various types of glass-forming liquids [5], local order can nonetheless be described in terms of degree of polymerization, formation of channels or sublattices, or formation of interpenetrating networks. Like the advancement of a chemical reaction, such structural features may be described in terms of the aforementioned parameter ξ . In internal thermodynamic equilibrium, i.e. in the liquid state, ξ is equal to $\xi_{eq}(T, P)$, but not in the glass transition range where $\xi(t)$ becomes a function of $T(t)$, $P(t)$, and $A(t)$, revealing its nonequilibrium nature. Below the glass transition range, where the relaxation time of the configurational degrees of freedom exceeds the experimental timescale, they cease to contribute to the measured property. At temperature low enough, the structure then eventually freezes in for good in one state defined by one particular value of $\xi(t)$, which becomes independent of the external parameters T and P .

From a practical standpoint, the timescale defined by the viscosity of the material is important to determine the temperature at which the system will fall out of equilibrium when observed at the timescale of a particular experiment. There is not yet a unique model for describing relaxation phenomena in all glass-forming liquids (Chapter 3.7), whether *strong* or *fragile* with Arrhenian or non-Arrhenian viscosities, respectively [6]. In measurements of macroscopic properties, one nonetheless considers generally that experimental timescales τ_{exp} are of the order of $\tau_{exp} \sim 10^2 - 10^3$ seconds. The viscosity should then be of the order of 10^{12} Pa.s or 10^{13} P for structural relaxation to be complete under these conditions. To stress the usually tremendous variations of

viscosity down to the glass transition, it will suffice to note that the viscosities of stable liquids (i.e. above the melting or liquidus temperature) range from 10^{-3} to 10^2 Pa.s depending on chemical composition and structural type.

4 Glass as a Nonequilibrium Substance

Time-dependent effects appearing at the glass transition are clearly observed in the heat capacities measured for PVAc (Figure 2), which is a model polymeric system extensively studied because of its excellent glass-forming ability and standard T_g close to room temperature. The observed hysteresis loop between cooling and heating demonstrates that the heat capacity does not only depend on T and P but also on time. Moreover, upon heating, the heat capacity shows a typical overshoot, i.e. an endothermic event, named structural recovery process. To come back to the initial liquid state, the system needs to recover the amount of internal enthalpy that has previously been lost. From such measurements, it is possible to determine the configurational contribution to the heat capacity ΔC_p^{conf} . Here, it is defined by the difference at every temperature between the heat capacities actually measured and estimated for the glass phase:

$$\Delta C_p^{\text{conf}} = C_p - C_p^g. \quad (6)$$

This type of definition also applies to other thermodynamic variables such as the thermal expansion coefficient α_p , or the isothermal compressibility κ_T . A configurational contribution consequently represents the thermodynamic contribution that originates in configurational changes in the liquid.

The glassy state then is defined as that for which the configurational movements have been frozen-in, i.e.

$\Delta C_p^{\text{conf}} = 0$. In this state, only the vibrational motions, i.e. the fast degrees of freedom (faster than the experimental timescale), contribute. To define this contribution over the entire temperature interval of interest, an extrapolation of the glass heat capacity from low to high temperatures is needed (Figure 2). The heat capacity of the supercooled liquid can also be extrapolated toward low temperatures (Figure 2). The difference between these values for the supercooled liquid and the glass,

$$\Delta C_p^{\text{conf,eq}} = C_p^l - C_p^g \quad (7)$$

then yields the equilibrium configurational contribution, which keeps increasing below T_g even though the actually observed values do vanish (Figure 3).

From the equilibrium and actual configurational contributions, the variation of the configurational enthalpy ΔH^{conf} and entropy ΔS^{conf} , taken between two temperatures, are calculated with:

$$\begin{aligned} \Delta H^{\text{conf}}(T) &= \int_{T_1}^T \Delta C_p^{\text{conf}} dT \text{ and } \Delta S^{\text{conf}}(T) \\ &= \int_{T_1}^T \frac{\Delta C_p^{\text{conf}}}{T} dT, \end{aligned} \quad (8)$$

where $T_1 = 360$ K is in Figure 2 an arbitrarily selected reference temperature.

Absolute values of both state functions could be obtained from the enthalpy and entropy of an isochemical crystalline compound through the crystallization values of these functions (see Figure 1). For lack of such a compound for PVAc, only relative values are thus presented (Figure 4) in such a way that both the actual and equilibrium values are equal from 360 K to the temperature of about 315 K at which internal equilibrium is lost. Since these variations are similar for the configurational enthalpy and entropy, only the former is shown in Figure 4.

Figure 2 Heat capacity of PVAc measured across the glass transition range by differential scanning calorimetry at the same rate of 1.2 °C/min first upon cooling (solid circle) and then upon heating (empty circle). Dashed lines: fits made from the heat capacities measured for the glass and supercooled liquid.

Figure 3 Configurational heat capacity of PVAc across the glass transition range upon cooling: configurational contribution (solid circle) and equilibrium configurational contribution (empty circle).

Figure 4 Difference between the configurational enthalpy of PVAc and a zero reference-value taken at 360 K. Actual value (solid circle) and equilibrium value (empty circle). Inset: magnification of Figure 4 showing extrapolated values of the glass and supercooled liquid of this differential configurational enthalpy intersecting at the point M , which defines the limiting fictive temperature $T_M = T_f'$.

Contrary to their equilibrium counterparts, which continue to decrease upon cooling, both the actual configurational enthalpy and configurational entropy level off in the amorphous state (Figure 4). Owing to the large width of the glass transition range, the heat capacity variations at the glass transition are much too smooth to be interpreted as reflecting the discontinuity of a second-order phase transition. Such a discontinuity can nonetheless be identified at a temperature T_M defined by the intersection of the extrapolated glass and supercooled liquid (Figure 4, inset). Both configurational enthalpy and entropy are thus continuous at that temperature, which separates the glass from the supercooled liquid. The same applies to other properties such as volume. Because entropy and volume are the first derivatives of the Gibbs free energy with respect to temperature and pressure, respectively, the following relations initially derived by Ehrenfest should hold when second-order derivatives of the free energy vary discontinuously at this point M :

$$\left. \frac{dP}{dT} \right|_M = \frac{\Delta\alpha_P}{\Delta\kappa_T} \quad (9a)$$

$$\left. \frac{dP}{dT} \right|_M = \frac{\Delta C_P}{T_M V_M \Delta\alpha_P}. \quad (9b)$$

To express these equations in terms of discontinuities of equilibrium configurational contributions at T_M , e.g. $\Delta C_P^{\text{conf,eq}}$ of Eq. (7), Prigogine and Defay [7] assumed that the supercooled liquid is in internal equilibrium down to T_M (i.e. $A = 0$ and $dA = 0$) whereas the glass below T_M is defined by $d\xi = 0$. These two equalities can then be grouped to yield the so-called Prigogine–Defay (PD) ratio [7]:

$$\Pi = \frac{\Delta C_P \Delta\kappa_T}{T_M V_M (\Delta\alpha_P)^2}. \quad (10)$$

Table 2 Thermodynamic parameters measured from five different glass-formers.

Material	T_g (K)	ΔS_0 (J/K/mol)	PD ratio	T_K (K)	T_0 (K)
SiO ₂	1480	5.1	$>10^3$	1150	NA Arrhenius relaxation
CaAl ₂ Si ₂ O ₈	1109	36.2	1.5–22	815	805
Glucose	305	1.7	3.7	241	242
PVAc	301	NA No crystal	2.2	239	250
Glycerol	183	19.4	3.7	134	123
Se	295	3.6	2.4	207	226

The values are taken from the literature.

Although considering an internal parameter ξ , this approach assumes that the glass transition occurs continuously at T_M where $\xi_g = \xi_l$. If so, it would follow from Eq. (9) that the PD ratio should be unity. As indicated by the values listed for widely different glass-forming liquids (Table 2), however, calculated PD ratios are higher or even much higher than unity. One can explain such values by taking into account the kinetic nature of the glass transition [8]. Physically, it is making sense to assume that isobaric temperature derivatives such as ΔC_p or $\Delta \alpha_p$ are not measured under the same kinetic conditions as an isothermal pressure derivative like $\Delta \kappa_T$. Whereas this inconsistency may be removed if more than one internal order parameters ξ are involved in the thermodynamics of the glass transition [9], the problem may in contrast be compounded by the uncertainties arising from the extrapolation procedures used for deriving the relevant parameters at the temperature T_M .

Another puzzling fact has been long ago pointed out by Kauzmann [10] who wondered what would happen if the entropy of a supercooled liquid were extrapolated down to temperatures much lower than the experimentally observed T_g . The conclusion was that it would become lower than that of the isochemical crystal at a temperature T_K , thus termed the Kauzmann temperature (Table 2), which could suggest that the liquid undergoes a continuous phase transition toward the crystalline phase at T_K analogous to the critical point of fluids.

One way out of the paradox implies kinetic arguments and assumes that the viscosity of the supercooled liquid diverges at a temperature close to T_K . This assumption may be represented by the Vogel–Fulcher–Tamman (VFT) equation (Chapter 4.1):

$$\eta = A \exp \left(\frac{B}{T - T_0} \right), \quad (11)$$

where the temperature T_0 of the viscosity divergence is actually close to the Kauzmann temperature (Table 2)

even though they may depend on the specific sample and the method of measurement.

Another way out is to take with great caution the extrapolations of the heat capacity and other thermodynamic functions of the supercooled liquid. As long pointed out [e.g. 11], there is no current theory for these properties in liquid state analogous to the Einstein or Debye models that provide functional forms at all temperatures for heat capacities of crystals.

As derived from strikingly old questions in glass science, these counterintuitive features indicate that glasses cannot be described by equilibrium thermodynamic states only. Nonequilibrium thermodynamics is, therefore, likely to be useful to characterize glasses and the glass transition.

5 Nonequilibrium Thermodynamics of the Glass Transition

The questions raised by the Kauzmann paradox or the PD ratio clearly illustrate the need for a more fundamental thermodynamic description of the glass transition. Following the pioneering work of Tool [12, 13] and Davies and Jones [9], different approaches and phenomenological models have been developed to deal with the glass transition range itself, many within the framework of classical nonequilibrium thermodynamics [4, 11].

The starting point has been the phenomenological concept of fictive temperature (T_f) propounded by Tool [12, 13] to characterize the state of a relaxing system at any time. This temperature is similar to an order parameter ξ . It thus overcomes the limitations of the fixed limiting temperature T_M , which characterizes only the point at which internal equilibrium is suddenly lost in a quenched state. On an analogous basis, a more detailed description is made in terms of two-temperature thermodynamics [14] whereby the vibrational and configurational degrees

of freedom are distinguished by a “classical” temperature for fast modes (phonons bath), and an effective temperature for the slow modes, respectively.

The first physical models have then relied on two different approaches. In free-volume theories, one generally considers that the dynamics of the system is determined by the free space present around its atoms, which makes configurational rearrangements more or less easy. In entropy theories, among which that of Adam-Gibbs is the best known [15], the same determining role is attributed to configurational entropy. In other words, these theories assign the strong increase of relaxation times with decreasing temperatures and the eventual structural freezing in to decreases of either free volume or configurational entropy. Other more recent theories of the glass transition rely on mode coupling, random first-order transitions or energy-landscape descriptions [e.g. 16]. These different approaches have the common goal of finding the exact expression for the structural relaxation time, or its distribution, as a function of controlling parameters such as temperature or pressure, or structural order parameter.

For the sake of simplicity, let us consider here conditions of constant pressure. If the additional parameter ξ is taken into account, the total differential of the enthalpy of a system can be written as the sum of two contributions (considering pressure, the generalization to three contributions would be obvious):

$$(dH)_P = \left(\frac{\partial H}{\partial T}\right)_{P,\xi} dT + \left(\frac{\partial H}{\partial \xi}\right)_{P,T} d\xi. \quad (12)$$

The isobaric heat capacity is written as:

$$C_P = \left(\frac{dH}{dT}\right)_P = \left(\frac{\partial H}{\partial T}\right)_{P,\xi} + \left(\frac{\partial H}{\partial \xi}\right)_{P,T} \left(\frac{d\xi}{dT}\right)_P. \quad (13)$$

The first term on the right-hand side is the heat capacity at constant ξ , i.e. C_P^{glass} , and the second, the configurational contribution ΔC_P^{conf} as defined by Eq. (6). To account for the kinetic nature of the glass transition, it is then necessary to rewrite Eq. (13) as:

$$C_P = \left(\frac{\partial H}{\partial T}\right)_{P,\xi} + \left(\frac{\partial H}{\partial \xi}\right)_{P,T} \left(\frac{d\xi/dt}{dT/dt}\right)_P. \quad (14)$$

When the rate of change of ξ becomes much smaller than the rate of change of temperature, $(d\xi/dt)_P \ll (dT/dt)_P$, the configurational contribution is negligible.

Hence, it is the ratio between these two rates that is controlling the relative value of the experimentally recorded configurational heat capacity. This ratio is maximum in the supercooled liquid state, and decreases throughout the glass transition range to become

negligible in the glassy state (cf. Figure 3). There, only the first right-hand side term in Eq. (14) contributes:

$$\begin{aligned} C_{P,\xi} &= C_P^{\text{glass}} < C_P < C_P^{\text{eq}} \\ &= C_P^{\text{liquid}} \text{ or } 0 < \Delta C_P^{\text{conf}} < \Delta C_P^{\text{conf,eq}}. \end{aligned} \quad (15)$$

The next step thus consists in taking into account the time dependence of ξ at every temperature through the temperature dependence of the relaxation time τ . The simplest way to do this is to assume a simple exponential decay for ξ at fixed temperature and pressure:

$$\frac{d\xi}{dt} = -\frac{(\xi - \xi_{\text{eq}})}{\tau}, \quad (16)$$

where $\xi_{\text{eq}}(P, T)$ is the equilibrium value of the order parameter, i.e. a variable characterizing the liquid structure that depends only on P and T . Although the relaxation time itself has been given different temperature dependences with Arrhenius, VFT, or others laws (Chapter 3.7), the important point is that they are all of an exponential nature with respect to T or P to ensure the structural freezing-in of the system.

Interesting applications of these concepts have been made with the lattice-hole model of liquids, which has the advantage of lending itself to an evaluation of the order parameter ξ . Schematically, this model considers a liquid as a lattice in which disorder is represented by unoccupied sites whose fraction x depends on both temperature and pressure [17]. From the equilibrium value of the order parameter, it is thus possible to solve the linear differential Eq. (16) to find its temperature dependence and, then, to calculate the variations of the heat capacity within the glass transition range under varied conditions [18]. Likewise, the configurational Gibbs free energy may also be computed analytically as a function of temperature, pressure, and order parameter. A similar approach has been followed to incorporate the effects of pressure in the expression of the structural relaxation time for determining also how the heat capacity, thermal expansion coefficient, and isothermal compressibility vary under different conditions [19].

From the configurational Gibbs free energy calculated for the lattice-hole model, one readily simulates with the definition (3) of the affinity its variations upon vitrification (cooling) and structural recovery (heating) [19]. Thermodynamic data measured on *o*-terphenyl may be used to simulate the corresponding affinities during temperature ramps (Figure 5): cooling at 0.3 K/min from an initial temperature of 255 K is followed by heating at the same rate, and then by further cooling at 0.5 K/min preceding final heating at 20 K/min. That the supercooled liquid begins to lose internal equilibrium from 248 K is indicated by the departure at this temperature of the affinity curve from the zero line, which represents the

Figure 5 Simulated affinities of *o*-terphenyl in the glass transition range upon cooling and heating as calculated from the lattice-hole model. Solid circle for -0.3 K/min and solid square for -0.5 K/min; empty circle for $+0.3$ K/min and empty square for $+20$ K/min. The horizontal line represents equilibrium ($A = 0$). Inset: entropy production rates calculated from the previous affinities. Solid circle upon cooling and empty circle upon heating.

maximum (equilibrium) value of the affinity during cooling. The affinity then linearly decreases with temperature below 240 K in the glassy state, with higher values for slower cooling as a result of lower glass transition temperatures. Upon heating, the affinity begins to increase linearly according to the same line pathway before crossing the equilibrium line. It then exhibits a peak whose position shifts toward higher temperatures and whose magnitude and width increase with the heating rate in ways such that the configurational heat capacity and the other thermodynamic coefficients can be simulated [19].

The entropy production can also be calculated from Eq. (4) (inset in Figure 5). In agreement with previous results [18], it shows a single peak upon cooling but two peaks upon heating. With respect to the experimental data, the advantage of the calculation is thus to distinguish clearly two contributions to the entropy produced when heat is brought to the material. The first peak is associated with a decrease of the configurational energy of the system, which is taking place because of the delay introduced by the relaxation time, even though heat is being supplied. As to the second peak, it is in contrast associated with the configurational energy necessary to recover internal equilibrium in the supercooled liquid state.

Here the wording “is associated” instead of “represents” is necessary because the entropy produced and configurational entropy changes necessarily differ as a result of the irreversible nature of the glass transition. Whereas the entropy production is the product of the thermodynamic force and flux (see Eq. (4)), the variation of the configurational entropy is written as, see Eqs. (8) and (13):

$$\frac{dS^{\text{conf}}}{dt} = \frac{\Delta C_p^{\text{conf}}}{T} \times \frac{dT}{dt} = \frac{(\partial H / \partial \xi)_{p,T} (d\xi/dt)_p}{T}. \quad (17)$$

The rate of entropy production thus reflects the spontaneous or irreversible microscopic processes that take place within the system during relaxation. As dictated by the Second Law of thermodynamics, it is always positive whether upon cooling or heating (Figure 5, inset). Physically, it can be thought of the heat irreversibly generated by friction at a microscopic scale. The resulting thermal power $P_i = T\sigma_i$, where σ_i is the entropy creation in Eq. (4), is produced much too quickly to be compensated instantaneously by an exchange of heat with the surrounding heat bath. Under this circumstance, this is why an effective or fictive temperature can be defined. This surrounding heat bath is sometimes called the phonon bath since it is characterized by fast or vibrational modes.

On the contrary, the change in configurational entropy is a reversible process related to the heat exchanged with the surrounding heat bath whose relevant thermal power is:

$$P_{\text{th}} = T \frac{dS^{\text{conf}}}{dt} = \Delta C_p^{\text{conf}} \times \frac{dT}{dt}. \quad (18)$$

Because the configurational entropy becomes constant upon vitrification, its variations have vanished (i.e. the configurational heat capacity) below the glass transition range. Above this range, in the supercooled liquid state, they of course differ from zero as indicated by

$$\begin{aligned} \frac{dS^{\text{conf,eq}}}{dt} &= \frac{\Delta C_p^{\text{eq}}}{T} \times \frac{dT}{dt} \\ &= \frac{(\partial H / \partial \xi)_{p,T}^{\text{eq}} (d\xi_{\text{eq}}/dT)}{T} \times \frac{dT}{dt}. \end{aligned} \quad (19)$$

In the transition range, the variations of the configurational entropy of the system are consequently positive or negative upon heating and cooling, respectively. As

already evaluated long ago either theoretically [9] or experimentally [20, 21], the entropy produced is generally negligible with respect to the configurational entropy changes. The integration of the heat capacity curves measured by calorimetry is thus a pertinent way to access to the absolute value of the residual entropy at 0 K [3]. As seen from a direct comparison of Eqs. (4) and (17), arriving at this conclusion is tantamount to neglecting the affinity with respect to the enthalpy of advancement of the configurational change at every temperature:

$$\text{Entropy production negligible} \iff A \ll \left(\frac{\partial H}{\partial \xi} \right)_{P,T} \quad (20)$$

6 Physical Aging

Relaxation times that depend only on temperature and pressure have been considered. Nevertheless, the complexity of microscopic structures in glasses implies the existence of a distribution of relaxation times. Relaxation processes then also depend on the instantaneous state of the system itself and, thus, on its history as, for instance, described by the Tool–Narayanaswamy–Moynihan model (Chapter 3.7, [22, 23]). A consequence is that some non-trivial relaxation processes can take place well below the glass transition range. Hence, it is interesting to study such a time-dependent process termed *physical aging*, which has a practical relevance through its possible effects on glass properties.

The process can be illustrated with DSC scans for PVAc (Figures 2 and 6). If the sample is cooled down at some rate to 297 K, i.e. about 10 K below the calorimetric T_g , and its temperature is kept constant for a time interval t_a , then its enthalpy (and entropy) relax to their lowest equilibrium values for the temperature (and pressure)

considered. Experimentally, physical aging manifests itself as differences between the areas of DSC scans upon heating recorded for samples annealed (72 hours at 297 K) and not annealed. For the experiment without annealing, the lowest temperature of 278 K has been directly reached (see cooling curve in Figure 6). The amount of enthalpy relaxed during aging is equal to the difference between the light gray and dark gray areas in Figure 6. Of course, for a given annealing temperature, such a difference increases with the aging duration. As recently carried out on polymeric glass-formers annealed at relatively low aging temperatures for a very long time, calorimetry (DSC) can bring to light two different timescales for glass equilibration, revealing the complexity and richness of relaxation processes well below T_g [24].

Phenomenologically, however, in simple cases aging can be accounted for with the same approach as developed in previous sections. It is related to the relaxation of the order parameter ξ toward its equilibrium value $\xi_{eq}(P, T)$ whereas the affinity A is relaxing at the same time toward zero. When applicable, the lattice-hole theory can be used to solve Eq. (16) at constant P and T to reproduce the observed process. As done for *o*-terphenyl [19], the order parameter is calculated at constant pressure and aging temperature $T = 229.5$ K with Eq. (16) and a temperature- and pressure-dependent relaxation time [19]. The affinity has been calculated upon heating at 60 K/min, either after cooling at 6 K/min without aging, or after cooling at the same rate but with an aging process at 229.5 K (Figure 7). Upon isothermal aging, the affinity increases markedly (see the arrow in Figure 6) and then increases at the same rate as without aging. The difference is that the zero line is crossed at a lower temperature so that a much bigger peak is observed when the affinity finally recovers its zero equilibrium value at high temperatures. Since the affinity is an integrated measure of the heat capacity, the large peaks either calculated or

Figure 6 Effect of aging on the heat capacities of PVAc recorded upon heating at the same rate. Heat capacity after a cooling (solid circle with line) and heat capacity after cooling and 72-hour annealing at 297 K (empty circle with line). The enthalpy released during aging estimated by the difference between the two areas included between these two curves. Heat capacities upon continuous cooling shown as solid circles.

Figure 7 Effect of aging on affinities calculated with the lattice-hole model upon heating at the same rate of 60 K/min, first after a continuous cooling at 6 K/min (black line with solid circle), and second after annealing at 229.5 K (black line with empty circle). The black arrow simulating the relaxation of affinity upon aging at 229.5 K. Affinity upon continuous cooling shown as solid circles.

observed for these properties are clear signatures of aging [19]. More complex calculations can of course be made to deal with at least two separate timescales [24], or a more realistic distribution of relaxation times.

7 Perspectives

Whether in the form of affinity, fictive temperature, or structural order parameter, additional variables must be introduced to deal with the nonequilibrium thermodynamics of glass-forming systems and, in particular, with the time dependence of their properties in relaxation regimes. Phenomenological advances now make it possible to predict these properties as a function of time and temperature or to determine accurately the entropy irreversibly produced, but the mechanisms involved at the atomic or molecular level generally remain to be deciphered. The physical nature of the glass transition is a case in point, as are the origins of Kauzmann catastrophe, of the strong variations of the PD ratio, of the diversity of relaxation timescales or of, as illustrated by the well-known memory effects, the complex nonlinear coupling of the parameters of the differential equations with which these processes are described.

Not only could highly sensitive calorimetric experiments yield valuable original data in this respect but coupling of different techniques such as dielectric spectroscopy and temperature-modulated calorimetry should bring new insights on the dynamics and thermodynamics of the glass transition. Recent experiments on ultra-stable organic glasses obtained by vapor

deposition techniques are, for instance, promising [25, 26]. And whereas very long aging performed well below T_g should also give new clues on the laws driving complex relaxation processes in the glassy state [24], experiments made at extremely rapid timescales (e.g. spectroscopy) are in contrast needed to investigate relaxation in supercooled liquids where equilibrium is quickly achieved. To give a single example, ultrastable organic glasses obtained by vacuum-deposition techniques should be of special interest in view of their internal stability that is equivalent of that of hyper-aged glasses (with aging time of millions of years) obtained by conventional melt cooling [25]. For this particular class of glasses, the aforedefined T_M values are so much lower (by a few tens of degrees) than the standard glass transition temperatures that T_M and T_g cannot be indiscriminately used in Eq. (9b) [25, 26]. Among other consequences, new insights should then be gained on the non-unity of the PD ratio. Finally, such experiments should of course be firmly complemented by fundamental work. Microscopic theories and atomistic simulations must be developed and, as stringent tests of their value, their predictions checked in terms of macroscopic physical properties.

Acknowledgments

The authors thank J. Richard for data treatments and simulations carried out with the lattice-hole model, G. McKenna for PVAc samples, and the reviewers for their time, remarks, and useful corrections.

3.3

The Glass Transition and the Entropy Crisis

Purushottam D. Gujrati

Department of Physics, Department of Polymer Science, The University of Akron, Akron, OH, USA

1 Introduction

Vitrification [1–3] is a prime example of an irreversible process going on at low temperatures T_0 or high pressures P_0 of the surrounding medium (which may be different from those of the system of interest). It is commonly believed now that almost all materials including organic and inorganic substances, man-made polymers, metals, plastics, biomaterials, drugs, etc., can be turned into a glass (or vitrified) with a suitable technique (Table 1). But our understanding of the glassy state (GS) is far from complete, mainly because they exhibit a *duality* in their properties, appearing either liquid- or solid-like at long or short timescales, respectively [2]. Molecular motions in liquids become progressively slower as vitrification is approached, with a characteristic time increasing from nanoseconds to beyond feasible experimental timescales time τ_{exp} (the inverse of the probed frequency ω) of the order of 10^2 to 10^5 seconds, i.e. one day (Chapter 3.7). This results in an operational definition of a range of temperatures T_{og} -to- T_{OG} for the glass transition (GT). Following convention, however, we simply use T_{og} as the transition temperature to specify this range, which is determined by the rate of approach to the transition.

The slow glassy dynamics is thought to occur because particles form cooperative groups of increasing sizes, which then define a *correlated length* as the ratio $\zeta_0 \equiv P_0/T_0$ increases. This is the idea behind the celebrated Adam–Gibbs theory [7] of the GT. A similar time dependence is also found in spin glasses, which exhibit an exponentially large number of metastable states below

the (spin-)GT temperature due to the presence of *frustration*, namely, the inability of the system to minimize simultaneously the (sometimes competing) interaction energies between its constituents. This similarity has suggested frustration to be also important for a regular glass [8], although the situation is not very clear.

There are many excellent recent monograph and reviews [3, 8–10] on glasses, from which the present chapter differs by its emphasis on nonequilibrium thermodynamics and its attempt to identify the communal entropy and the free volume to provide a thermodynamic unified approach to glasses [11]. We do not specifically discuss the actual form of the temporal variation except to note that the most common empirical law, valid in a limited domain, is the Kohlrausch stretched exponential $q(T_0, t) = q_0 \exp(-t/\tau)^\beta$ [8, 9], where the property q and some average *relaxation time* τ must be state-dependent quantities. In the next section, we review some important concepts and theories. It is followed by a description of glassy phenomenology in Section 3. Nonequilibrium thermodynamics used here is briefly introduced in Section 4, and its consequences for glassy relaxation are considered in Section 5. The topics of free volume and the communal entropy are taken up in Section 6. We follow this by a resulting unifying approach in Section 7. The final section contains a discussion of the results and the limitation of the approach. The present chapter partially complements the previous one.

2 Important Concepts and Theories

2.1 Fast and Slow Modes

There is a hierarchy of relaxation modes [11] in a glass. Phenomenologically and for the sake of simplicity, however, we can broadly speaking divide them into at least

Diopside	1005	637	Anorthite	1160	815	[5, 6]

Figure 1 The 2-D projection of a typical 3-D trajectory for 100 min for $\phi = 0.56$. Most of the time, particles are confined to their cages. Occasionally, a particle will move a long distance and get trapped in another cage. In the figure, the particle took 500 seconds to shift its position. Source: Reprinted with permission from [12].

two distinct and widely separated timescales governing fast and slow modes in glasses. The former refers to the localized oscillations of the particles (atoms, molecules, segments, monomers, etc.) in the cells or cages formed by neighboring particles, and the latter to the translation and diffusion (translation over long distances [1]) of particles. In Figure 1, we show a two-dimensional projection of a three-dimension trajectory of a colloidal particle at high enough density, which oscillates within its cage for a long time before leaving to a new cage in which it oscillates again to leave it later on, and so on. These two distinct modes distinguish the glass from other nonequilibrium states where there is only one mode to be considered. Owing to its complexity, and its incomplete and sometimes controversial understanding, vitrification continues to attract researchers to this date.

2.2 What Is a Glass?

As a physicist, we first need to ask is: What is a glass? The simple and most common answer is that glass or GS is a time-dependent nonequilibrium state of matter [2, 3, 13] found at low temperatures T_0 and/or high pressures P_0 of the surrounding medium. It undergoes GT from a relatively brittle solid glass into a molten state (the super-cooled liquid [SCL]) as ζ_0 decreases. The striking feature of a glass, which distinguishes it from an equilibrium crystal (CR), is that it has much higher potential energies [14]. Even at absolute zero, there remains a non-zero gap between their energies. Thus, a glass can be thought of as a macrostate which has trapped a lot of frozen defects relative to the crystal that were present in the equilibrium liquid (EL) at the melting point [15]. Glass is

Figure 2 Schematic variation of the volume as the liquid is cooled. The freezing transition from the equilibrium liquid (line above T_{0m}) to the crystal (shown by the green line) occurs at T_{0m} ; the latter becomes perfectly ordered at absolute zero. Bypassing crystallization leads to the supercooled liquid (shown by the line as the continuation of the equilibrium liquid). The supercooled liquid bends continuously without any discontinuity in the slope into different glasses (shown by different broken lines) at different glass transition temperatures (T_{0g}) depending on the rate of cooling r . As r decreases, T_{0g} also decreases (shown by arrows becoming larger), until finally it converges to its limit T_{0k} under infinitely slow cooling rate ($r \rightarrow 0$) but now with a discontinuity in the slope. This limit is called the *ideal glass transition temperature* or the *Kauzmann temperature*, and the corresponding glass shown by the dashed curve is time-independent and is called the *ideal glass* (IG). A similar variation of the slopes of the density is also seen when we increase P_0 at a fixed T_0 ; we merely replace T_0 in the figure by $1/P_0$. Thus, we can replace the horizontal axis by $1/\zeta_0$.

most commonly prepared in the laboratory by cooling or compressing the SCL to fall out of equilibrium (Figure 2). The genuine equilibrium state corresponds to the crystal. This does not mean that the SCL can never be treated as in equilibrium; its stationary limit, called the equilibrium supercooled liquid (ESCL) with a stretch of imagination, can be treated as an equilibrium state under the restriction that only *disordered* microstates are considered [15], a sensible restriction to study glasses. The simplest way to identify these microstates is to introduce an order parameter ρ . It is defined so that $\rho = 0$ for disordered states and $\rho \neq 0$ for ordered states [15]. We denote the restricted space of disordered microstates by $\mathcal{D}$, and refer to the restriction as a *restricted ensemble* formalism in this work to distinguish it from an *unrestricted* ensemble in which *all* microstates are considered. To make a clear distinction, all possible time-dependent SCL states will be called nonequilibrium supercooled liquid (NESCL) states; they occur near but below the bends and are shown as dotted curves, whereas the continuous line refers to the ESCL. In the following, we will use the SCL to refer to both nonequilibrium and equilibrium SCLs. The GS

shown by a broken line is always treated as out of equilibrium and exists way below the bend.

The standard formulation of entropy

$$S(t) = - \sum_k p_k \ln p_k \geq 0 \quad (1)$$

in terms of microstate probability p_k of the *allowed* k th microstate is applicable to any (equilibrium or nonequilibrium) state in both ensembles [16]; p_k depends on the extensive observables (the energy E , volume V , number of particles N , etc.) in addition to the time t . In the stationary limit so that p_k has no t -dependence, these entropies achieve their unique maximum value S_{ESCL} or S_{IG} (S_{CR}) in the restricted (unrestricted) ensemble below T_{0M} . Above T_{0M} , they yield S_{EL} in both ensembles, as expected. In the stationary limit, the entropy is related to the number of microstates W in both ensembles by the famous Boltzmann formula $S = \ln W$ (we set the Boltzmann constant $k_B = 1$ so that the entropy becomes dimensionless).

2.3 Adam–Gibbs Theory

The excess entropy defined as

$$S_{\text{SCL}}(T_0, t) \equiv S_{\text{CR}}(T_0) + S_{\text{ex}}(T_0, t), T_0 < T_{0M} \quad (2)$$

has played a very pivotal role in the field of GT. Kauzmann [13] proved that it exhibits a rapid drop below T_{0M} by for many systems. A smooth *extrapolation* to lower temperatures shows that it eventually vanishes at some temperature below T_{0M} , and becomes *negative* if *extrapolated* to lower temperatures. A (kinetic) transition, i.e. a GT takes place at a higher temperature T_{0g} to avoid this *entropy crisis*, known commonly as the *Kauzmann paradox*. In the limit of zero cooling rate r (not accessible in experiments or simulations, but accessible in a theoretical setup), the GT occurs in the ESCL at $T_0 = T_{0\text{ex}}$ [$S_{\text{ex}}^{\text{ESCL}}(T_{0\text{ex}}) = 0$], see Figure 2, and is known as the *ideal glass transition* (IGT) from the ESCL liquid to an ideal glass below $T_{0\text{ex}}$. It should be stressed, however, that there is no thermodynamic requirement for $S_{\text{ex}}(T_0)$ to be non-negative. There are physical systems like He^4 in which $S_{\text{ex}}(T_0)$ can become negative at low temperatures. This means that the vanishing of $S_{\text{ex}}(T_0)$ *cannot* be an argument for a GT but the vanishing of the communal entropy $S_{\text{ESCL}}^{\text{comm}}(T_0)$, to be defined later, will be as we will discuss.

The thermodynamic theory due to Adam and Gibbs [3, 7–10, 15, 17] attempts to provide a justification of the *entropy crisis* in the ESCL by specifically considering the configurational entropy $S^{\text{conf}}(t) \doteq S(t) - S^{\text{kin}}(t)$ among the positions and interactions (which we take to be independent of momenta) among the particles [15]. Here, $S^{\text{kin}}(t)$ is entropy originating from the kinetic energy of the particles and its separation from $S(t)$ is possible

because the internal energy E can be partitioned into two *independent* contributions from the positions (configurations) and momenta (kinetic energy) of the particles, respectively. In a lattice model such as in the Gibbs–DiMarzio theory [18], $S^{\text{conf}} = S(t)$ as there is no kinetic energy. We must be careful not to confuse $S^{\text{conf}}(T_0, t)$ with $S_{\text{SCL}}(T_0, t)$ as they are different quantities. The central idea in the Adam–Gibbs theory is that the sluggishness observed in a system is a manifestation of the smallness of the configurational entropy, i.e. the smallness of the available configurations to the system. From this theory, it follows that the viscosity $\eta(T_0)$ above the GT is given as follows:

$$\ln \eta(T_0) = A_{\text{AG}} + B_{\text{AG}}/T_0 s^{\text{conf}}, \quad (3)$$

where A_{AG} and B_{AG} are system-dependent constants and $s^{\text{conf}} = S^{\text{conf}}/N$. It is commonly believed that the configurational entropy also vanishes at a positive temperature $T_{0\text{S}}$ (where $\eta(T_{0\text{S}})$ diverges), which is not identical to $T_{0\text{ex}}$, although they are close [17]. The derivation of Eq. (3) is based on the concept of cooperative domains of size z , which gradually increases as the temperature is lowered and diverges at $T_{0\text{S}}$. At this temperature, the entire system acts like a cooperative domain. While this particular domain is disordered, its configurational entropy must vanish in this theory. As the laboratory GT temperature $T_{0\text{g}}$ occurs at about 50 K above $T_{0\text{S}}$, the value of z at $T_{0\text{g}}$ is much smaller; it is of the order of 5–10.

2.4 Free Volume Theory

The cell theory of liquids is very appealing to study the motion of individual particles [1, 3] during a GT. The localized oscillatory motion of a particle occurs around the minimum of the potential ϕ generated by its neighbors in the cell. (The set of minima from all the cells determines what is nowadays called the *inherent structure* [3].) Such a motion occurs at all times in the crystal unless there are interstitial vacancies. In a glass, such a motion occurs at short time and endows a glass with solid-like properties (Figure 1). But at long times, there occurs uninhibited translation and diffusion, superimposed on the oscillatory motion controlled by a continuously changing ϕ as the neighbors change [1]. This gives a glass a liquid-like property, whose central feature is the mobility of the particle.

At high densities, the neighbors impede the motion in almost all directions and the motion becomes confined within the cell with little or no diffusion. At low densities, the particle can move almost freely in any direction and diffusion occurs. (The presence of chemical bonding requires the whole molecule to move together and must be eventually accounted for.) As we are interested in the

dense phase, we have both motions possible at different timescales. The ability to move long distances requires what is vaguely termed the *free volume* V_f , and which is *communally* shared by many particles. It gives rise to the *fluidity*. The potential ϕ felt by the particle in its cell endows the particle with what can be termed the *interaction volume* v_i per particle: it is the volume necessary to execute its oscillatory motion in ϕ ; the latter must gradually become very steep as the particle gets close to the neighbors. At low temperatures, these steep portions have almost no chance to be explored by the particle. Therefore, the interaction volume v_i must be usually smaller than the cell volume Δ . Their difference $\Delta - v_i$ gives the particle some elbow room for translation and must be included in V_f . The determination of $V_i \equiv Nv_i$ is somewhat technical and will be discussed later. In terms of the interaction volume V_i , we have

$$V = V_i + V_f; \quad (4)$$

both components are functions of state variables.

Many workers use the concept of occupied volume $V_o \equiv Nv_o$ to define $V_f = V - V_o$. However, the concept may be ambiguous [19]. For some, v_o is just the van der Waals volume, also known as the molecular volume v_m . It is just a parameter of the liquid. In contrast, the interaction volume is theoretically well defined in our approach. To inquire if they are the same is meaningless. As a van der Waals volume is merely a parameter, V_o is just a constant equal to Nv_m . Such a definition will not account for the sudden change in the temperature variation (the slope) of the ideal glass volume at the kink in Figure 2. Our definition of V_i allows for such a variation.

The free volume theory of Doolittle [17, 20] has attempted to describe the GT with some respectable success even though lately it has fallen out of favor. This is unfortunate as it captures the essence of the GT, which then occurs when the free volume becomes sufficiently *small* to impede the *mobility* of the molecules [20]. The Doolittle equation correctly predicts the abrupt increase in the viscosity for a large number of glass formers in a narrow range over which v_f becomes very small [17]. According to this equation, the fluidity ϕ , which is basically the inverse of the viscosity η , is given by

$$\phi \equiv \eta^{-1} = \phi_0 \exp(-\gamma v_m/v_f), \quad (5)$$

where γ is a fitting parameter of order unity. Phenomenologically, we identify a GT to occur normally when $\eta \gtrsim 10^{13}$ poise or $\tau \simeq \tau_{\text{exp}}$; see the upper axis in Figure 2. In the Doolittle equation, the parameters γ and v_m are *constant*. But in general, these parameters must be functions of the state variables. With this dependence, we will refer to the above equation as the *generalized Doolittle equation*. The free-volume picture provides a very nice way to think of the GT [1] with percolation of the free volume

as an important ingredient [17]. The time dependence of the free volume redistribution, determined by the energy barriers encountered during it, should provide a *kinetic* view of the transition, and must be properly accounted for. This approach is yet to be completed to satisfaction. One finds that a linear temperature-dependent $v_f = a(T_0 - T_{0V})$, $T_{0V} \neq 0$, a and T_{0V} constants, is satisfied only over a narrow range of the temperature T_0 for most substances [17]. Assuming the linear dependence, we find that $\eta(T_0)$ diverges near T_{0V} according to the phenomenological Vogel–Tammann–Fulcher equation

$$\ln \eta(T_0) = A_{VTF} + B_{VTF}/(T_0 - T_{0V}), \quad (6)$$

where A_{VTF} and B_{VTF} are system-dependent constants (Chapter 4.1). At T_{0V} , V_f vanishes so that there cannot be any translational motion, i.e. any flow, which is consistent with a diverging $\eta(T_{0V})$. The system becomes completely *jammed* [8]. The entropy associated with the translational motion, which we call the *communal entropy* S^{comm} , must also vanish (Section 6.2). The temperature where $S^{\text{comm}} = 0$ will be denoted by T_{0K} in this chapter, and our attempt is to define V_f such that $T_{0V} = T_{0K}$.

The vanishing of V_f is reflected in the variation of the volume; see the point on the lowest curve at temperature T_{0K} in Figure 2, where there is a sharp kink and a discontinuity in the slope. (We have identified the temperature as T_{0K} rather than T_{0V} with the anticipated result obtained later that the Kauzmann temperature T_{0K} , where the communal entropy vanishes, is the same as T_{0V} . This is, as it should be, because the ideal glass shown by the dashed line must be a *unique* state.) This curve is the result of extrapolation $r \rightarrow 0$ to obtain the ESCL (solid curve) and the ideal glass (dashed curve); as a result, there is a singularity at T_{0K} . The presence of free volume above T_{0K} gives rise to different expansion coefficients on the two sides of T_{0K} (Figure 3b). In contrast, the communal entropy does not vanish in Figure 3a so there is no IGT at a positive temperature in this case. The free volume and S^{comm} do not vanish for the laboratory glasses shown by the upper two curves in Figure 2.

Similar to the Kauzmann temperature T_{0K} for isobaric vitrification at fixed P_0 , a Kauzmann pressure P_{0K} can also be identified in the ESCL where $S_{\text{ESCL}}^{\text{comm}}(P_0) = 0$ as the pressure is increased at fixed T_0 . We will collectively call them Kauzmann points.

2.5 Random First-Order Theory

An alternative thermodynamic theory for the impending entropy crisis based on spin-glass ideas has also been developed in which proximity to an underlying first-order transition is used to explain the GT [10]. The theory is

Figure 3 Schematic variation of the communal entropy S^{comm} (a) of the equilibrium supercooled liquid (solid curve) and a possible time-dependent supercooled liquid, which turns into a glass (dotted curve) during vitrification. It is assumed that there is no ideal glass transition in the equilibrium supercooled liquid. The transition region between T_{0g} and T_{0G} has been exaggerated to highlight the point that the glass transition is not a sharp point. For all temperatures $T_0 < T_{0g}$, the nonequilibrium supercooled liquid undergoes isothermal (fixed temperature T_0) structural relaxation in time toward the equilibrium supercooled liquid. The entropy of the equilibrium supercooled liquid is shown to extrapolate to zero, but that of the glass to a nonzero value $S_R > 0$ at absolute zero. (b) S^{comm} of the equilibrium supercooled liquid for a system with an ideal glass transition at T_{0K} , below which we obtain the ideal glass for the equilibrium supercooled liquid. In the restricted ensemble, S^{comm} for the equilibrium supercooled liquid becomes negative below T_{0K} . We conjecture that for all glass-forming systems, the correct form of S^{comm} for the equilibrium supercooled liquid in (a) is the one shown in (b) with an ideal glass transition.

based on the one-step replica symmetry breaking in spin glasses. The one-step replica symmetry breaking is identified in a long-range spin glass model so the theory is at a mean field level. Whereas some may consider this to be a weakness of the theory, it also provides a new level of intuition about ordinary glasses.

2.6 Mode-Coupling Theory

The mode-coupling theory [8] is an example of theories based on kinetic ideas, which deals not with the GT but with the transition at the mode-coupling temperature $T_{MC} > T_g$. Thus, it is not directly relevant for our review. This theory may be regarded as a theory based on first-principle approach, which starts from the static structure factor. In this theory, the ergodicity is lost completely, and structural arrest occurs at T_{MC} .

3 Nonsingular Glass Phenomenology

3.1 The Restricted Ensemble

As is well known, singularity at a phase transition emerges as the system makes a transition between two *distinct* equilibrium phases such as at T_{OM} between the

EL (disordered) and the crystal (ordered); see the vertical dashed line at T_{0M} in Figure 2. In equilibrium, it is customary to introduce an unrestricted *partition function* Z , which exhibits a singularity at T_{0M} [14]. If the transition is somehow avoided such as during supercooling in which we continue from the equilibrium to the ESCL, then one describes such a process by considering the restricted ensemble involving $\mathcal{D}$ [15]. The corresponding restricted partition function $Z_{\mathcal{D}}$, as noted above, does not exhibit any singularity at T_{0M} as both sides represent the same (disordered) state corresponding to $\rho = 0$. By considering the restricted partition function $Z_{\overline{\mathcal{D}}}$ involving ordered microstates ($\rho \neq 0$), which again does not show any singularity, and comparing the two free energies $F_{\mathcal{D}} = -T \ln Z_{\mathcal{D}}$ and $F_{\overline{\mathcal{D}}} = -T \ln Z_{\overline{\mathcal{D}}}$, we identify T_{0M} by their crossing. The singularity at T_{0K} , the sharp kink in Figure 3b, is due to a *phase transition* between the ESCL and the ideal glass in the restricted ensemble involving $\mathcal{D}$.

If we introduce $\mathcal{D}'$ as the set of disordered microstates from which we remove all microstates belonging to $\overline{\mathcal{D}}$ associated with the ideal glass, then the corresponding partition function $Z_{\mathcal{D}'}$ can be used to describe the ESCL without any singularity at T_{0K} ; above T_{0K} , $\mathcal{D}'$ is inconsequential [15] so $F_{\mathcal{D}} = F_{\mathcal{D}'}$. In particular, we see from Figure 2 that the ESCL volume V_{ESCL} obtained by using $\mathcal{D}'$ will show no singularity at T_{0K} and can be continued *mathematically* to lower temperatures, except that V_f will become negative under this continuation. Thus, the continuation does not give a physical state, which is reminiscent of the Kauzmann paradox. The singularity at T_{0K} is inferred by the crossing of the free energies $F_{\mathcal{D}'} = F_{\mathcal{D}}$ and $F_{\overline{\mathcal{D}'}}$. It is the absence of a singular behavior in $F_{\mathcal{D}'}$ that is of primary interest here. This is also reflected in the absence of a singularity in the corresponding entropy $S_{\mathcal{D}} = S_{\mathcal{D}'} = -\partial F_{\mathcal{D}'} / \partial T$.

3.2 Absence of a Singularity in Laboratory Glasses

The relaxation time τ of the system, which is independent of τ_{exp} , usually increases monotonically with ζ_0 ; see the upper axis in Figure 2. The SCL remains in equilibrium in $\mathcal{D}$ shown by the solid curve as long as $\tau < \tau_{\text{exp}}$, but begins to fall out of the restricted equilibrium at T_{0g} and becomes a NESCL as soon as $\tau_{\text{exp}} < \tau$. The system is not really frozen yet, but eventually turns into a glass when $\tau > \tau_{\text{exp}}$ at a somewhat lower temperature T_{0G} (not shown in Figure 2, but shown in Figure 3a, where we show the entropy), when the system has no discernible mobility. The loss of mobility results in “freezing” of the system *without* any singular changes in its thermodynamic densities in the GT region $\Delta T_G \doteq (T_{0g} - T_{0G})$. The state below T_{0G} is identified as a glass. There are

no singularities at the GT temperatures of the two laboratory glasses in Figure 2 or the laboratory glass in Figure 3a. The respective curves smoothly connect with the ESCL. Thus, the *experimental glass transition* should be thought of as a crossover phenomenon with a gradual turnover of the ESCL through a NESCL into a glass over a temperature range. As the curves emerge out of the ESCL continuously, there is no mathematical singularity for the top two curves in Figure 2.

3.3 Ideal Glass: Analytic Continuation

The continuous curve in Figure 3a shows $S_{\mathcal{D}} = S_{\mathcal{D}'} = S_{\text{ESCL}}$ of the ESCL. The dotted curve shows S_{GS} , which extrapolates to a positive value of the residual entropy S_R at absolute zero [15]. In contrast, it is commonly believed that S_{SCL} extrapolates to zero at $T_0 = 0$, even though there are no thermodynamic requirements for this.

While Figure 3a does not show any IGT, Figure 3b does at $T_{0K} > 0$, where S^{comm} vanishes. At this point, the ESCL will undergo a phase transition into the ideal glass. We see that the ideal glass has a zero communal heat capacity (heat capacity associated with S^{comm}), but the ESCL has a nonzero communal heat capacity. Thus, the ideal glass and the ESCL are distinct states. As noted above, the transition will result in a singularity in the thermodynamic free energy. Despite this singularity, each state itself is nonsingular in the restricted ensemble. For example, S_{ESCL} can be mathematically extended to temperatures below T_{0K} , although it will result in negative S^{comm} . This is similar to the Gibbs–DiMarzio theory, in which analytically continued $S_{\text{ESCL}}^{\text{conf}}$ becomes negative below the IGT.

4 Nonequilibrium Formulation: Brief Review

The nonequilibrium formulation presented here is a condensed version of our previous presentation elsewhere [11, 16]. The system that undergoes vitrification is represented by Σ . We treat it as an interacting system by embedding it in a medium $\tilde{\Sigma}$; their combination forms an isolated system Σ_0 . Quantities pertaining to Σ_0 will have a suffix 0, while those for $\tilde{\Sigma}$ will have a tilde; quantities for Σ will have no suffix. The medium is taken to be extremely large compared to Σ so that the latter does not affect the fields of $\tilde{\Sigma}$. Thus, its fields $\tilde{T}$, $\tilde{P}$, etc., will be denoted by T_0 , P_0 , etc., of Σ_0 . We will also find it convenient to use the term body to denote any one of Σ , $\tilde{\Sigma}$, and Σ_0 . The quantities pertaining to a body will not have any suffix.

Let Σ be in a nonequilibrium state such as a glass. Its entropy $S(t)$ must obey the second Law, i.e. the Law of increase of entropy, according to which the *irreversible* (denoted by a suffix i) entropy $d_i S$ generated in any infinitesimal physical process within a body satisfies the inequality $d_i S \geq 0$; the equality occurs for a reversible process. This entropy is generated within the system because of dissipative processes. Thus the suffix i can also stand for “internal.” The quantity $d_e S$ with a suffix “e” will denote the entropy exchange with the medium (the “exterior”). In general, we can identify $d_e X$ and $d_i X$ for the change $dX = d_e X + d_i X$ in any extensive quantity X . Therefore, $dS = d_e S + d_i S$. As there is no *exchange* entropy change ($d_e S_0 = 0$) for Σ_0 , we have $dS_0 = d_i S_0 \geq 0$ during any process. For Σ_0 in equilibrium, $dS_0 = 0$ so that $S_0 = \text{constant}$.

4.1 Concept of a Nonequilibrium State and of Internal Equilibrium

4.1.1 An Isolated Body

For Σ_0 in equilibrium, S_0 can be expressed as a *state function* $S_0(\mathbf{X}_0)$ of its extensive observables (E_0 , V_0 , N_0 , etc., that can be controlled by an observer) denoted by $\mathbf{X}_0$, from which follows the Gibbs fundamental relation for the entropy S_0 ,

$$dS_0 = \sum_p (\partial S_0 / \partial X_{0p}) dX_{0p}; \quad (7)$$

the partial derivatives are related to the constant *fields* of the system:

$$(\partial S_0 / \partial E_0) = 1/T_0, (\partial S_0 / \partial V_0) = P_0/T_0, \dots \quad (8)$$

As $\mathbf{X}_0$ remains constant, S_0 remains constant and has the maximum possible value given by the Boltzmann formula $S_0(\mathbf{X}_0) \equiv \ln W_0(\mathbf{X}_0)$, where $W_0(\mathbf{X}_0)$ is the number of microstates corresponding to the observable $\mathbf{X}_0$. This conclusion about the entropy when it is a state function will play an important role below.

For Σ_0 out of equilibrium, S_0 is no longer a constant. The nonequilibrium state will continuously change, which is reflected in its entropy increase in time. This requires expressing its entropy as $S_0(\mathbf{X}_0, t)$ with an *explicit time-dependence*. If it happens that the changes in S_0 and the state come from the variations of additional independent variables, whose set is denoted by ξ_0 , that keep changing with time until the body comes to equilibrium [21, 22], then S_0 can be expressed as a function of $\mathbf{X}_0$ and ξ_0 with no explicit time dependence: $S_0(\mathbf{Z}_0(t))$, where $\mathbf{X}_0$ and ξ_0 is collectively written as $\mathbf{Z}_0$. As the variables in ξ_0 continue to change in time for the isolated system, they cannot be controlled by the observer; thus, they are known as the *internal variables*. We can identify $\mathbf{Z}_0(t)$ as the set of *nonequilibrium state variables* so that the

entropy becomes a state function of $\mathbf{Z}_0(t)$. We can extend Eq. (7) to

$$dS_0 = \sum_p (\partial S_0 / \partial Z_{0p}) dZ_{0p}; \quad (9)$$

the new derivatives $(\partial S_0 / \partial \xi_{0p})$ determine the *affinities* $A_{0p}(t)$,

$$(\partial S_0 / \partial \xi_{0p}) = A_{0p}(t) / T_0(t). \quad (10)$$

All fields and affinities continue to change in time until Σ_0 reaches equilibrium. As Σ_0 comes to equilibrium, all $A_{0p}(t)$ vanish, which requires that ξ_0 are no longer independent of $\mathbf{X}_0$.

A body for which the entropy has become a state function of $\mathbf{Z}_0(t)$ is said to be in *internal equilibrium*. As there is no explicit time dependence, the entropy in internal equilibrium remains constant for the given state variables. The situation is no different than when Σ_0 was in equilibrium. Thus, $S_0(\mathbf{Z}_0(t))$ in this case has its maximum possible value for given $\mathbf{Z}_0(t)$, and is given by the Boltzmann form $S_0(\mathbf{Z}_0(t)) \equiv \ln W_0(\mathbf{Z}_0(t))$, where $W_0(\mathbf{Z}_0(t))$ is the number of microstates corresponding to the state variable $\mathbf{Z}_0(t)$. For a body not in internal equilibrium, the entropy must retain an explicit time-dependence so that the derivatives in Eq. (8) *cannot* be identified as state variables like, temperature, pressure, etc.

4.1.2 An Interacting Body

An interacting body (a body in a medium) out of equilibrium with its medium will also require internal variables. For the body in internal equilibrium, the derivatives $((\partial S / \partial E) = 1/T(t), (\partial S / \partial V) = P(t)/T(t), (\partial S / \partial \xi_p) = A_p(t)/T(t) \dots)$ of its entropy S give the fields $T(t)$, $P(t)$, $A_p(t) \dots$ etc. The corresponding Gibbs fundamental relation is given by

$$dS(t) = \sum_p (\partial S / \partial Z_p) dZ_p. \quad (11)$$

4.1.3 A Simple Example for an Internal Variable

Consider an isolated body Σ_0 formed by two parts Σ_1 , Σ_2 that are initially at different temperatures $T_1(0)$ and $T_2(0)$. We imagine their volumes and particle numbers as fixed, but allow their energies $E_1(t)$, $E_2(t)$ to change with time through their mutual thermal contact. We know that eventually, they come to equilibrium at the same common temperature T_{0f} . During this time, their temperatures keep changing. The total energy $E_0 = E_1 + E_2$ is constant. The entropy S_0 is the sum of the entropies S_1 and S_2 of the two parts. Thus, S_0 is a function of two variables $E_1(t)$, $E_2(t)$. If we want to express S_0 as a function of E_0 , we need another *independent* variable $\xi_0(t)$, which is evidently a function of the difference $E_1(t) - E_2(t)$. We take $\xi_0(t) \equiv [E_1(t) - E_2(t)]/2$. This makes S_0 a function of E_0 and ξ_0 . The affinity $A(t) = \partial S_0 / \partial \xi_0$ is

$$A(t) = 1/T_1(t) - 1/T_2(t)$$

and vanishes in equilibrium, as expected. Here, $T_1(t)$ and $T_2(t)$ are the instantaneous temperatures of the two parts and are given by $1/T_1(t) = (\partial S_1/\partial E_1)$, $1/T_2(t) = (\partial S_2/\partial E_2)$.

4.2 Gibbs Free Energy of an Interacting System

From now on, we will only consider the system in internal equilibrium. We will further simplify our discussion by mostly considering one internal variable ξ and restrict the observables to E , V , and N for simplicity. Moreover, we will keep N fixed so that it will not be shown explicitly and allow the possibility of fluctuating E and V due to exchanges with the medium. The medium is always taken to be in equilibrium with its fields and affinity given by T_0, P_0 and $A_0 = 0$; the system achieves these values when it comes to equilibrium with $\tilde{\Sigma}$. In terms of $H(t) \equiv E(t) + P_0 V(t)$, $G(t) \equiv H(t) - T_0 S(t) = E(t) - T_0 S(t) + P_0 V(t)$, which are the time-dependent enthalpy and the Gibbs free energy, respectively, of the system Σ , it is easy to show that [22]

$$S_0(t) - \tilde{S}_0 = S(t) - H(t)/T_0 = -G(t)/T_0, \quad (12)$$

where $\tilde{S}_0 \equiv \tilde{S}(E_0, V_0, \xi_0)$ is a constant, which is independent of the system. Here, $S(t)$ and $S_0(t)$ are the entropies of Σ and Σ_0 . It immediately follows from this that $dG/dt = -T_0 d_i S_0/dt \leq 0$, as expected. We similarly have $dH/dt = T_0 d_e S/dt = d_e Q/dt$, where $d_e Q = T_0 d_e S$ is the heat exchange with $\tilde{\Sigma}$.

4.3 Thermodynamic Forces for Relaxation

The Gibbs fundamental relation can be written as

$$dE(t) = T_0 dS(t) - P_0 dV(t) + (T(t) - T_0) dS(t) - (P(t) - P_0) dV(t) - A(t) d\xi(t). \quad (13)$$

Using the first Law $dE(t) = T_0 d_e S(t) - P_0 dV(t)$, we find

$$T_0 d_i S(t) = (T_0 - T(t)) dS(t) + (P(t) - P_0) dV(t) + A(t) d\xi(t) \geq 0. \quad (14)$$

Each of the three terms on the right must be non-negative in accordance with the second Law

$$(T_0 - T(t)) dS(t) \geq 0, (P(t) - P_0) dV(t) \geq 0, A(t) d\xi(t) \geq 0. \quad (15)$$

The prefactor $T_0 - T(t)$, etc., in each equation represents a *thermodynamic force* that drives the system toward equilibrium.

5 Nonequilibrium Relaxation in Internal Equilibrium

5.1 Thermodynamic Relaxation

During isobaric vitrification, the system Σ , originally in equilibrium with a medium at T'_0, P_0 , is suddenly brought into another medium at T_0, P_0 at time $t = 0$. As Σ is out of equilibrium, it will strive to equilibrate irreversibly ($d_i S/dt > 0$). The resulting process is called relaxation during which various thermodynamic quantities will undergo irreversible changes dictated by the second Law, which we now investigate.

5.1.1 Heuristic Consideration

As Σ has no time to interact with the new medium at $t = 0$, its initial temperature $T(0)$ is the original temperature T'_0 . As Σ eventually comes to equilibrium, we must have $T(\tau_{eq}(T_0)) = T_0$, where $\tau_{eq}(T_0)$ is the time required to come to equilibrium. Thus, $T(t)$ continues to fall during relaxation from T'_0 to T_0 . Accordingly, the heat exchange $d_e Q = dH < 0$. Thus, the enthalpy decreases during relaxation, which is an experimental fact [2]. Similarly, the initial entropy $S(0)$ is the entropy $S_{ESCL}(T'_0)$ of the higher temperature. After equilibration, $S(\tau_{eq}(T_0)) = S_{ESCL}(T_0)$. Since the entropy increases with temperature, we conclude that the entropy also falls during relaxation from $S_{ESCL}(T'_0)$ to $S_{ESCL}(T_0)$ at $t = \tau_{eq}(T_0)$.

5.1.2 Thermodynamic Support

We now support this intuitive picture by the nonequilibrium thermodynamics of the previous section. Here, we closely follow [22]. It is easy to see from Eqs. (13) and (14) that

$$\begin{aligned} \frac{d_i S(t)}{dt} &= \left(\frac{1}{T(t)} - \frac{1}{T_0} \right) \frac{dE(t)}{dt} + \left(\frac{P(t)}{T(t)} - \frac{P_0}{T_0} \right) \frac{dV(t)}{dt} + \left(\frac{A(t)}{T(t)} \right) \frac{d\xi(t)}{dt}. \end{aligned} \quad (16)$$

Each term on the right side must be nonnegative in accordance with the second Law. Let us assume that in an *isobaric* vitrification, $P(t) = P_0$. In this case, we find by combining the first two terms in Eq. (16) that

$$(1/T(t) - 1/T_0) dH(t)/dt \geq 0. \quad (17)$$

As $dH(t)/dt < 0$ experimentally [2] and theoretically as noted above,

$$T(t) > T_0 \quad (18)$$

during relaxation so that $T(t)$ approaches T_0 from above [$T(t) \rightarrow T_0^+$]. It now follows from the first inequality in Eq. (15) that during vitrification

$$dS(t)/dt \leq 0. \quad (19)$$

A more refined and general argument for the validity of Eq. (19) is also available [11].

5.2 Microstate Probabilities in Internal Equilibrium

For a body in internal equilibrium, the situation is very similar to that of a body in equilibrium. Thus, the maximization of entropy results in a very similar formulation of the microstate probabilities. The equilibrium probabilities are given by $p_{keq} = \exp[-\beta_0(E_k + P_0 V_k)]/Z_{eq}$, where Z_{eq} is the equilibrium partition function, $\beta_0 = 1/T_0$, and E_k , V_k are the energy and volume of the k th microstate. For the body in internal equilibrium, the microstate probabilities are given by

$$p_{ki-eq} = \exp[-\beta(t)\{E_k + P(t)V_k + \mathbf{A}(t) \cdot \boldsymbol{\xi}_k\}]/Z_{i-eq}, \quad (20)$$

where Z_{i-eq} is the internal equilibrium partition function; $\beta(t) = 1/T(t)$, and $\boldsymbol{\xi}_k$ is the set of internal variables for the k th microstate. The particle number N , which is held fixed in both cases, is not shown. In terms of the number of microstates $W(E, V, \boldsymbol{\xi})$ corresponding to E , V and $\boldsymbol{\xi}$, Z_{i-eq} is given by

$$Z_{i-eq} = \sum_{E, V, \boldsymbol{\xi}} W(E, V, \boldsymbol{\xi}) \exp[-\beta(t)\{E + P(t)V + \mathbf{A}(t) \cdot \boldsymbol{\xi}\}]; \quad (21)$$

it differs from Z_{eq} due to the presence of $\boldsymbol{\xi}$ and time-dependent fields/affinities.

6 The Free Volume and the Communal Entropy

6.1 The Cell Theory

The simplest model to account for the nonzero particle size is described by the van der Waals' equation

$$(P + N^2 a/V^2)(V - Nb) = NT,$$

where a accounts for the intermolecular attractive forces and the "free volume" is given by $V - Nb$. The parameter b is half the volume of a sphere of radius $2r_0$, where r_0 is the "radius" of the particle [14]. It is the excluded volume for each particle and the presence of N in Nb implies its additivity. Indeed, it should be thought of as the "thermodynamic" volume of a particle, which is determined by

the interactions with its neighbor. One uses the cell theory of liquids to go beyond the van der Waals theory. Here, V is divided into N cells (such as the Voronoi-type cells) of an average volume Δ per particle (Figure 4), where we show the possible cell arrangement for disordered (liquid or gas) in (a) and ordered (crystal) states in (b). Each cell has a single particle within it as shown. For molecules with connectivity such as polymers (Chapter 8.7), one must take proper care of all *distinct* placements of monomers that respect their connectivity. For example, if we consider a disordered conformation of a polymer with 17 monomers, then we must consider all distinct conformations of the polymer even though each conformation has a single monomer in the 17 cells in (a). Thus, there will be many more microstates for the cell pattern in (a) when connectivity has to be incorporated. There will be a single microstate if there is no connectivity to consider. This poses no conceptual problem as the average of any observable O in the cell model is given by the standard formulation $\bar{O} \equiv \sum_k O_k p_{ki-eq}$, where O_k is the value of O for the k th microstate and the sum is over all *distinct* microstates. It is then clear that the entropy associated with local motion in the cell potential also contains what is commonly known as the *conformational entropy* due to different conformations of a molecule such as a polymer.

The nonuniform model in (a) for the disordered state is a generalization of the uniform model traditionally used in cell theories. The other difference is that we allow for an internal variable. The motion of each particle within its cell is governed by ϕ due to all its neighbor, which we denote by $\phi(\mathbf{r}|\{\mathbf{r}'(t)\})$, where $\mathbf{r}$ is the position of the particle under consideration within its cell and $\{\mathbf{r}'\}$ denotes the set of the continually changing positions of all its neighbors in time. The connectivity among the

Figure 4 Cell representation of a small region of disordered (a) and ordered (b) configurations at full occupation: each cell contains a particle. Each cell representation uniquely defines a potential well or basin in the potential energy landscape. Each particle is surrounded by four particles in the ordered configuration, but not for the disordered configuration. In the hole theory, some of the cells remain empty.

neighbors and the particle must be properly accounted for in this set. The probability $P(\phi)$ for the potential $\phi(\mathbf{r}|\{\mathbf{r}'(t)\})$ is given by the following identity

$$P(\phi) = \sum_k' p_{ki-\text{eq}} \quad (22)$$

where the prime over the sum implies that the sum is restricted to those microstates in which the particle and its neighbors are restricted to be at $\mathbf{r}$ and $\mathbf{r}'$, respectively.

The volume Δ must be at least as big as needed to allow for the local oscillations. The cell potential can be used to characterize the *interaction volume* v_i : it is the minimum volume needed for the allowed local motion. One way to quantify v_i is by the root-mean square of the displacement during the local motion as follows. The average over all possible cell potentials with probability $P(\phi)$ of the displacement squared is given by

$$r_{\text{rms}}^2 \equiv \sum_{\phi} P(\phi) \left[\frac{1}{\tau_{\phi}} \mathbf{r}^2(t) dt \right], \quad (23a)$$

where $\mathbf{r} = 0$ is taken to be at the minimum of the potential. The inner integral is over the time period τ_{ϕ} of an oscillation controlled by ϕ . We first observe that r_{rms} changes with the temperature. To see this most clearly, we simply consider an interparticle harmonic potential ϕ . From dimensional analysis alone, we conclude that the mean square displacement of all the particles scales as the temperature: $\overline{r^2} \sim T(t)/k_s$, where k_s is the spring constant of the potential. Thus,

$$r_{\text{rms}}(T(t)) \sim [T(t)/k_s]^{1/2}, \quad (23b)$$

and vanishes at absolute temperature $T(t) = 0$. It usually happens that the oscillatory modes equilibrate rapidly with the medium. In that case, we must replace $T(t)$ by T_0 . At absolute zero, particles are sitting in the potential minima, and there is an average distance d_{min} between particles. Half of the average distance $r_{\text{min}} \equiv d_{\text{min}}/2$ is taken as the “radius” of the particle, which then determines its interaction volume v_m at absolute zero. This is the minimum of the interaction volume. The distance r_{min} should not be confused with the so-called radius r_0 of a particle corresponding to the “impenetrability” of the particles. The interparticle potential begins to rise steeply for separation between particles below the “radius” r_0 [14]. Thus, r_0 is not strictly the radius of a particle. As the temperature increases, the linear size of the particle increases due to oscillations and so does its interaction volume, which is now given by

$$v_i = \gamma(r_{\text{min}} + r_{\text{rms}})^3 \quad (24)$$

in terms of a geometrical factor γ of order unity. The above volume may be quite different from the customarily defined occupied volume v_o , which is commonly used

in the glassy literature. Unfortunately, there is a lot of ambiguity in the definition of v_o and how to obtain it theoretically [19] so we make no attempt to compare the two.

The difference $v_f = \Delta - v_i$ is the free volume v_f that is the elbow room for the translation and rotation of the center of mass of the particle. This motion gives rise to the diffusion of the particle from the region over which the local oscillatory motion occurs. As ζ_0 decreases, the elbow room, i.e. v_f increases (and so do Δ and v_i) but not so much so that particles are still confined within their respective cells. As the free volume increases further, the particles can escape to the neighboring cells so that sometimes a cell may have multiple occupancy of the particles. The particles will undergo local motion in the new cell before they make excursion to another neighboring cell. If the free volume increases too much, then diffusion becomes the dominant motion and the local motion is no longer possible as the particles are far apart now. A situation like this occurs in gases. The above is an average picture so that it will also occur through to fluctuations in energy, volume, and internal variables. The aforementioned scenario has been confirmed by numerical simulations that has been discussed by several authors; see, for example, Refs. [1, 22] and Figure 1.

The above discussion is equally valid for the disordered and ordered macrostate. We will, however, consider the disordered macrostate in the following.

An obvious refinement of the above cell theory is to allow for holes by having some empty cells. Their presence gives an additional contribution to the free volume. It also allows for a considerable variation in the number of neighboring particles due to the presence of holes, which makes this theory attractive. As the volume of a glass is considerably greater than that of the corresponding crystal or the ESCL, the glass has a significant number of holes, which decreases during relaxation. In general, the decrease in the free volume is related to the irreversible relaxation, whereas the decrease in the interaction volume is related to the equilibrium relaxation as noted above since the local motion within the cell potential occurs at the temperature T_0 of the medium and not at the instantaneous temperature of the glass; see also the discussion by Matsuoka [19]. The division of volume in the interaction and free volumes results in the two volumes to be independent as they refer to independent degrees of freedom. Their existence may be related to the success of the two-parameter model of Aklonis and Kovacs [23].

6.2 Communal Entropy

The communal entropy S^{comm} plays a central role in the study of glasses [1, 15, 17]. From the fact that entropy and

volume are both extensive, we find that the entropy density $\sigma = S/V$ is a *homogeneous function* of order zero. We can write the entropy as a sum of two terms: $S = V_i\sigma + V_f\sigma$ in which the two volumes must be extensive. This is a trivial identity but allows us to introduce two different entropy components associated with the two components of the volume. One such component is S^{comm} , which is associated with the translation of the particles. The free volume decreases as ζ_0 increases and inhibits the translation. The particles must be fully jammed if there is no elbow room ($V_f = 0$). In this state, there cannot be any translation and S^{comm} must also vanish. This identifies the ideal glass. If we wish to identify the communal entropy associated with the free volume, then it must vanish for the ideal glass. The only possible relationship between S^{comm} and V_f must be *linear* because of their extensivity. If we write it as $S^{\text{comm}} = V_f\sigma'$ with $\sigma' \neq \sigma$, then the other component $S^{\text{int}} = S - S^{\text{comm}}$, the interaction entropy, is given by $S^{\text{int}} = V_i\sigma + V_f(\sigma - \sigma')$. As S^{int} must be determined by the local motion within the cell potential ϕ , it depends on V_i but not on V_f . Hence, we take $\sigma' = \sigma$ and write

$$S(t) = S^{\text{int}}(t) + S^{\text{comm}}(t), S^{\text{comm}} = V_f\sigma, S^{\text{int}} = V_i\sigma; \quad (25)$$

each of the above two components of the entropy must be non-negative and must satisfy the second Law provided there is minimal coupling between the two kinds of motion. As said earlier, S^{int} includes the conformational entropy associated with different conformations of the molecules. The deep connection that we have discovered between the free volume and communal entropy shows that they vanish simultaneously in the ideal glass so that whether we vary the density (control variable P_0) or the entropy (control variable T_0), we obtain the unique ideal glass at the respective Kauzmann point. This, we hope, will clarify some confusion present in the field as we discuss now.

7 The Unifying Approach for Glasses

It becomes clear from the above discussion that one can consider several entropy differences (S_{ex} , S^{conf} , S^{comm} , etc.). Some will vanish, most probably at different ζ_0 , under extrapolation to higher ζ_0 . Similarly, various definitions of the free volume will also show that they vanish at different ζ_0 under extrapolation. Thus, unless care is taken, the vanishing of the entropy difference and the free volume will appear to be unrelated. This has created much confusion in the field. However, by a careful definition of the free volume and the relevant (communal) entropy, one ensures that they vanish simultaneously at

a point called the IGT point. At this point, they refer to the same unique macrostate; see Figures 2 and 3.

In the following, we are interested in the SCL in $\mathcal{D}'$. We will focus on the communal entropy for which we use S instead of S^{comm} for notational simplicity. We will exhibit E and suppress all other extensive observables below and use a single internal variable ξ for simplicity. According to the second Law $S_{\text{NESCL}}(E, \xi) < S_{\text{ESCL}}(E)$; see Figure 5 where various portions of entropy curves are also identified. As the slope of the curve FG determines the inverse of the internal temperature $T(t) \neq T_0$ of a NESCL, while that of the curve DFCK the inverse of the medium temperature T_0 , we conclude from the figure that $T_G(t)$ at E_G is higher than $T_K = T_{0K}$ at E_K . Indeed, as $T_{\text{NESCL}}(E) = T_{\text{ESCL}}(E)$ at $E = E_F$ and at $E = E_K$, where E_F is the energy at F, it is evident that $T_{\text{NESCL}}(t) > T_{0K}$ over FG. Here, we have used $E(t)$ to express $T(E)$ as $T(t)$. As $S_{\text{NESCL}}(E, V, \xi)$ has no singularity over its entire range KGF, we can expand $S_{\text{NESCL}}(E, V, \xi)$ in the form of a Taylor series over FG around the point K. For later applicability, it is useful to consider $S_{\text{NESCL}}(E, V, \xi)$ as a function of $T(t)$, $P(t)$ and $\xi(t)$. For the isobaric vitrification at P_0 that we are considering, we set $P(t) = P_0$. Introducing $\Delta T(t) \equiv T(t) - T_{0K}$ and $\Delta\xi(t) \equiv \xi(t) - \xi_{\text{eq},K}$ and recognizing that at K the heat capacity C_{PK} is nonzero but finite and that the affinity A_{0K} vanishes (as the ESCL represents equilibrium states in $\mathcal{D}'$), we immediately conclude that the leading terms in the expansion must be linear in $\Delta T(t)$ (no linear term in $\Delta\xi(t)$) and bilinear in $\Delta T(t)\Delta\xi(t)$. Thus, we can pull out ΔT from all the expansion terms to finally write in terms of a function Ψ_S whose definition is evident from the (infinite) Taylor expansion ($S_{\text{ESCL}}(E_K) = 0$):

$$S_{\text{NESCL}}(T(t), P_0, \xi(t)) = \Delta T(t)\Psi_S(T_{0K}, P_0, \Delta T(t), \Delta\xi(t)); \quad (26)$$

we have not shown any dependence on $\xi_{\text{eq},K}$ as it is a function of T_{0K} , P_0 so it is no longer independent. The extensive function takes the value $\Psi_S(T_{0K}, P_0, 0, 0) = C_{PK}/T_{0K}$.

A similar Taylor expansion can be made for the volume V_{NESCL} . We first recall that $V_{f,\text{NESCL}}$ and the communal entropy S_{NESCL} vanish simultaneously and that

$$S_{\text{NESCL}}(T(t), P_0, \xi(t)) = \sigma(T(t), P_0, \xi(t))V_{f,\text{NESCL}}(T(t), P_0, \xi(t)). \quad (27)$$

(In contrast, there is no such relationship between the configurational entropy and the free volume. The simplest way to appreciate is to recognize that the configurational entropy in the Gibbs–DiMarzio theory [18] is nonzero even when the polymers cover the entire lattice, which corresponds to zero free volume.) Thus, $V_{f,\text{NESCL}}$ is also non-singular and will have a Taylor expansion

Figure 5 Schematic form of communal entropies in $\mathcal{D}'$ for the equilibrium supercooled liquid and the nonequilibrium supercooled liquid in accordance with the second Law and the gap hypothesis [15]. The lowest possible energy of the equilibrium supercooled liquid is E_K and the corresponding entropy is given by the curve KCDF. It vanishes at K without any singularity. The point K represents the unique ideal glass whose entropy remains zero as shown by the ideal glass entropy OK (dashed line). The lowest possible energy of the nonequilibrium supercooled liquid, which emerges continuously out of the equilibrium supercooled liquid at point F, is shown to be $E_G > E_K$ at point G due to additional defects. It represents the entropy of a laboratory glass; it also has no singularity at point G so that it can be mathematically continued below E_G until it vanishes. As the disordered state of zero entropy must be unique, this continuation must terminate at point K with the same slope as of the curve KCDF. It is shown by the dashed curve GK. It is in essence similar to the continuation carried out by Kauzmann but for S^{comm} . We do not show the axis corresponding to the independent variable ξ , which is changing along the curve FG. (At points K and F, ξ is no longer independent). The slope at point G is lower than that at point K.

around the Kauzmann point. To determine the nature of the expansion, we follow the above method to determine the leading powers of $\Delta T(t)$ and $\Delta \xi(t)$. The volume expansion coefficient at K due to the free volume is nonzero as we approach K from the high temperature side because of the difference in the slopes at K in Figure 2. Thus, the expansion must start with a term linear in $\Delta T(t)$. The determination of the leading power of $\Delta \xi(t)$ requires considering the behavior of $(\partial V / \partial \xi)_{T,P}$. By considering the double Legendre transform $\hat{G} = E - T(t)S(t) + PV(t)$, which is a system-intrinsic internal Gibbs free energy, we find that $V = (\partial \hat{G} / \partial P)_{\xi,T}$ so that

$$(\partial V / \partial \xi)_{T,P} = (\partial^2 \hat{G} / \partial \xi \partial P) = (\partial A / \partial P)_{\xi,P};$$

we emphasize that $\hat{G}$ (even with $P = P_0$ as noted above) should not be confused with the Gibbs free energy $G(t) = E(t) - T_0 S(t) + P_0 V(t)$, which contains the temperature and pressure of the medium [14, 22]. It is the latter that decreases in a spontaneous process as discussed in Section 4.2. As the affinity A always vanishes at

K regardless of the pressure, the derivative on the right side vanishes at K. This means that $(\partial V / \partial \xi)_{T,P}$ also vanishes at K, which leads to a leading bilinear combination $\Delta T(t) \Delta \xi(t)$. Thus, the situation is as before for S_{NESCL} so that we can write a similar form for $V_{f,\text{NESCL}}$,

$$V_{f,\text{NESCL}}(T(t), P_0, \xi(t)) = \Delta T(t) \Psi_V(T_{0K}, P_0, \Delta T(t), \Delta \xi(t)). \quad (28)$$

We can use this form of the free volume in the Doolittle Eq. (5) to obtain

$$\eta = \eta_0 \exp(\gamma v_m / (T(t) - T_{0K}) \psi_V) \quad (29)$$

in terms of the intensive function $\psi_V \equiv \Psi_V / N$. We thus conclude that the phenomenological equation is a special case of the above general equation. The limited validity of the original (constant parameters) Doolittle equation also makes the VTF equation with limited validity. In addition, different concept of the free volume will also yield different temperatures where it vanishes. This explains the puzzling differences between T_{0V} and the Kauzmann temperature noted by several workers.

Using the linear relationship from Eq. (27) in Eq. (5), we obtain

$$\eta = \eta_0 \exp(\gamma v_m / g S_{\text{NESCL}}) \quad (30)$$

in terms of the per particle communal entropy $s_{\text{NESCL}} \equiv S_{\text{NESCL}} / N$ and $g = 1/\sigma$. This is the analog of the Adam–Gibbs Eq. (3) in terms of the communal entropy, except that the viscosity diverges at different temperatures in the two formalism. A similar argument as used above will also show that in terms of $\Delta T_S(t) \equiv T(t) - T_{0S}$,

$$S_{\text{NESCL}}^{\text{conf}}(T(t), P_0, \xi(t)) = \Delta T_S(t) \Psi_S^{\text{conf}}(T_{0S}, P_0, \Delta T_S(t), \Delta \xi(t)).$$

Thus, its vanishing at T_{0S} also shows a divergence of viscosity in Eq. (3).

As all these formalisms are developed based on different approaches but with the same conclusion of diverging viscosity, it appears that the suggestion of a rapid rise in the viscosity due to a sudden drop in some form of entropy difference seems very enticing. Thus, we are driven to the conclusion that we can treat the SCL GT within a thermodynamics formalism involving some sort of entropy crisis. However, the divergences occur at different temperatures so the divergences may be devoid of any physics in terms of ideal glass. This leaves the nature of the state with a diverging viscosity quite mysterious.

While the vanishing of free volume is not tied to the vanishing of s^{conf} or s_{ex} , it occurs simultaneously with the vanishing of the communal entropy. Thus, our proposal of using the communal entropy ties the divergence of the viscosity with the vanishing of either the free

volume or the communal entropy at the same temperature T_{0K} , and helps in elucidating the nature of ideal glass as a *jammed* state with no translational mobility and, hence, no communal entropy.

8 Perspectives

A complete understanding of viscosity divergence around GT is of technological importance. The conventional approaches to study viscosity as a function of temperature either uses ΔS_{ex} , S^{conf} , or V_f . Phenomenological data fitting invariably leads to a perplexing scenario in that the divergence occurs at different temperatures and does not unravel the root cause of the dynamical slowdown. This seems unsettling as the invariable conclusion is that there is no relationship between the vanishing of V_f , ΔS_{ex} , and S^{conf} as used in the experimental analysis. The puzzle is that the thermodynamic state of the system with a diverging viscosity must be independent of the theory used to describe the system. Such a state must be a unique state in that once the viscosity has diverged, the state cannot change in time unless disturbed.

With our current understanding of nonequilibrium thermodynamics, we have begun to unravel the mystery a bit by connecting the viscosity divergence with either the vanishing of the free volume or the communal entropy. This is done by properly identifying the two concepts thermodynamically. For a system in internal equilibrium, η must be a function of the state variables: $\eta = \eta(T(t), P(t), \xi(t))$. For a state with diverging viscosity, there cannot be any variations in the fields. In other words, we expect a unique temperature where η diverges. At this point, which identifies the Kauzmann temperature T_{0K} , the system mathematically turns into an ideal glass state characterized by vanishing S^{comm} and V_f simultaneously. This mathematical singularity appears as the sudden and rapid rise in the viscosity in laboratory glasses. Thus, the new approach provides a unified picture of the glassy behavior. While we did not discuss it here, we have shown it elsewhere [22] that our nonequilibrium thermodynamics also provides a rationale for the Tool–Narayanaswamy phenomenology (Chapter 3.7). It is evident that we can never get to the ideal state in the laboratory, but this is not relevant for the mathematical expansion around the Kauzmann point.

The linear relation $S^{comm} = V_f \sigma$ associated with the free volume V_f differs from the alternate choice $S_f = -\ln V_f$ used by several authors ([19], for example). We do not consider the latter choice as it cannot only give negative communal entropy, but also does not respect the extensivity of the two quantities.

The limitation of the chapter should be mentioned. We have not discussed recent work dealing with the heterogeneity in space and time for glasses. The reason for this is that the nonequilibrium thermodynamics that we are using requires the additivity of the entropy for different parts. This requires the parts to be macroscopically large so that surface effects can be neglected. Thus, the approach is not applicable to a few particles for which we need small-size nonequilibrium thermodynamics, a field which is in infancy at present. We have also not discussed how the notion of the free volume or the communal entropy can be extended to each microstate as it evolves in time. Such a study will provide more detailed information about the resulting fluctuations going on within the system.

Atomic Vibrations in Glasses

Bernard Hehlen and Benoît Rufflé

Laboratoire Charles Coulomb (L2C), UMR 5221 CNRS, Université de Montpellier, Montpellier, France

1 Introduction

Atoms have by definition essentially fixed position in a solid. Their only degrees of freedom are thus vibrations around these positions with amplitudes that increase with temperature. As a thermodynamic measure of these changes, the heat capacity then determines the temperature dependence of the internal energy, entropy, and other functions. But the relevance of atomic vibrations is not restricted to thermal properties because thermal energy is involved in any process where potential energy barriers must be overcome. This is the case of not only any kind of phase transformations, including magnetic or ferroelectric transitions, but also of transport of heat, electrically charged species, or atoms.

In a crystal, atoms do not vibrate independently from one another. Vibrations are instead described as a set of harmonic plane waves termed *phonons* whose energies are quantized, whose number and type are determined by the symmetry of the lattice, and whose frequencies vary with the wave vectors according to specific dispersion relations. Although the fundamental basis of *lattice dynamics* was laid down by Born and von Karman as early as 1912, the lack of spatial symmetry prevents this theory from being applied to amorphous solids. The problem of atomic vibrations in glasses has thus long been laid aside until the impressive development of new experimental techniques, computing capabilities, and theoretical advances has made it possible to tackle it fruitfully in the last past decades.

The connection between the macroscopic and microscopic aspects of atomic vibrations is most readily

established through the *vibrational density of states*, $g(\Omega)$, which is the distribution of the number of vibrational modes as a function of the frequency Ω . The vibrational isochoric heat capacity $C_v(T)$ is directly derived from $g(\Omega)$ through

$$C_v(T) = \int_0^{\Omega_m} c_v(\Omega, T) g(\Omega) d\Omega, \quad (1)$$

where Ω_m is the highest vibrational frequency. As for $c_v(\Omega, T)$, it is the heat capacity of a single oscillator given by the Einstein function.

$$c_v(x) = \frac{x^2 e^x}{(e^x - 1)^2}, \quad (2)$$

where $x = \hbar \Omega / k_B T$, and k_B and $\hbar$ are Boltzmann and reduced Planck constants, respectively.

In the last past decades, much progress has been made either theoretically or experimentally to determine $g(\Omega)$ as well as the various vibrational excitations existing in glasses. These advances will thus be reviewed in this chapter with a focus on low-temperature conditions under which a rich phenomenology manifests itself. When heat capacities are approaching their Dulong-and-Petit limits, which is already the case for oxide glasses near room temperature, significant effects of structure and composition on vibrational properties in contrast necessarily tend to vanish. This is why such high-temperature conditions will not be considered in this chapter.

The starting point will be the classical description of phonons in perfectly ordered structures with a simple one-dimensional model. The impact of disorder on the vibrational properties of the system will reveal the loss of the plane-wave character of the normal modes and the concomitant apparition of quasi-localized modes. We follow with the comparison between the low-temperature

Reviewers: P. Gujrati, Department of Physics, The University of Akron, Akron, OH, USA

R. Vacher, Laboratoire Charles Coulomb, Université de Montpellier, Montpellier, France

thermal properties of crystalline and disordered solids, underlining the relation between the well-known anomalous behavior of the latter materials and their vibrational properties. Finally, we discuss the implications for vibrational spectroscopy of sound waves and optic modes, including the boson peak.

2 Atomic Vibrations in Disordered Solids

2.1 The Diatomic Linear Chain

A simple system is a chain of N atoms of mass m alternating with N atoms of mass M to which they are connected by springs of force constant K . If periodic conditions are applied, the chain forms an infinite periodic lattice of unit cells comprising one of each mass. The solution to the equation for longitudinal motions is a set of well-defined propagating plane waves with eigenfrequencies Ω_j and associated wave vectors Q_j , which define two dispersion curves $\Omega_j(Q_j)$, namely, an acoustic and an optic branch representing in- and anti-phase motion of the masses within a unit cell, respectively. Each solution j is called a *normal mode* or an *eigenmode*. For the j th normal mode, the displacement of mass l of one species reads

$$U_{j,l}(t) = u_j \exp\left(i\left[Q_j r_l - \Omega_j t\right]\right), \quad (3)$$

where u_j is the amplitude of the mode and r_l is the position of the mass in the chain. At every moment, there exists a perfect spatial oscillatory pattern of the mass displacements $u_{j,l} = u_j \exp(iQ_j r_l)$, characterized by Q_j .

One can then introduce disorder by varying the spring constants K_i along the chain, the masses, or their equilibrium positions. Here, we will assume a normal distribution of spring constants with a mean value K_0 and a standard deviation δK to diagonalize the dynamical matrix and derive the eigenfrequencies and eigenmodes of the system. Owing to disorder, $U_{j,l}$ can no longer be simply expressed as in Eq. (3) so that it is no longer possible to define Q_j strictly. One can nevertheless expand $u_{j,l}$ in a Fourier series of the components Q_k with amplitudes $\alpha_{j,k}$ [1]. For a quasi-plane-wave normal mode j , the amplitude is significant only for $\alpha_{j,k}$ for which $j \approx k$. Conversely, a localized mode has a large range of nonzero $\alpha_{j,k}$. The nature of a normal mode j can thus be roughly characterized by the mean value $\bar{Q}_j$ and the standard deviation of its wave vector spectral density $|\alpha_{j,k}|^2$. These coefficients also control the response of the system to a plane-wave vibrational excitation [1]. As an example, eigenfrequencies Ω_j have been computed for a disordered chain comprising $N = 2000$ masses as a function of $\bar{Q}_j$ (Figure 1) with $\delta K/K_0 = 0.25$ and a mass ratio $M/m = 2$.

As noted long ago [2], the vibrational density of states of the disordered chain $g_d(\Omega)$ is not much affected by disorder, especially for the acoustic modes whose density is actually similar to that of a crystalline counterpart $g_c(\Omega)$. The main differences occur near termed frequencies where $g_c(\Omega)$ exhibits sharp maxima, which are termed *Van Hove singularities* and are smeared out by disorder (Figure 1b). Although this similarity is holding particularly true for optic modes, $g_d(\Omega)$ is higher than $g_c(\Omega)$ by only about 3% even at low frequencies, i.e. in the acoustic regime.

Figure 1 Vibrational properties of a disordered diatomic linear chain. (a) Eigenmode frequencies Ω_j as a function of the mean value $\bar{Q}_j$ of the wave vector spectral density $\alpha_j(Q)$ (dots); standard deviations of $\alpha_j(Q)$ centered on $\bar{Q}_j$ characterizing the Q -spread of the j th eigenmode (very thin horizontal lines); dispersion curves of the acoustic and optic modes of the ordered chain (thick oblique curves). (b) Vibrational density of states $g(\Omega)$ of the crystalline (dashed line, $g_c(\Omega)$) and the disordered chains (dotted line, $g_d(\Omega)$). (c) Displacement snapshots for the three eigenmodes indicated.

In contrast, the nature of the vibrational modes is strongly modified by disorder (Figure 1a and b). The progressive scattering of the initial plane waves is clearly illustrated by the wide Q -spread of the eigenmodes (Figure 1a). As generally found, the higher the frequency, the larger is the deviation from a plane-wave excitation. In the long-wavelength limit, the very low-frequency acoustic modes hardly differ from those of their crystalline counterparts. Details of the force constant distribution is indeed of little concern to these long-wavelength acoustic excitations as fluctuations are averaged out.

The eigenvectors (mass displacements) of these modes exhibit almost perfect oscillations in space as illustrated in Figure 1c by the lowest line corresponding to $\Omega_j = 0.02$. This is no longer true for $\Omega_j = 0.24$ for which the envelope of the mass displacements shows important spatial variations. This mode is still an extended (collective) mode as all the masses participate in the vibration, albeit with different amplitudes. The loss of the plane wave character increases dramatically for modes at higher frequency as shown for $\Omega_j = 1.61$ belonging to the optic branch in the crystalline chain. Most of the vibrational amplitude is localized on a couple of neighboring masses. All high-frequency modes show significant displacements of neighboring masses only, occurring at randomly distributed spatial positions. But these modes are not truly localized because their vibrational amplitudes are extremely small for many masses, but not exactly zero.

2.2 Real Amorphous Solids

Scattering of the vibrational modes thus increases with frequency even when elastic disorder is small enough that the vibrational density of states is similar to that of a periodic lattice. To what extent such a simple picture can be generalized has been much debated because real glasses combine positional, mass, and elastic disorder in complex 3-D structures made up of coupled structural entities. Further, disorder-induced mixing of transverse and longitudinal polarized excitations should arise at high frequency [1].

In the long-wavelength limit, sound waves propagate in glasses as they do in crystals. At that scale, amorphous solids are isotropic continuous elastic media whose low-frequency sound waves can still be reasonably described as quasi-plane-wave acoustic excitations. Phonon-like transverse acoustic excitations showing linear dispersion have been, for example, measured in vitreous silica [ν -SiO₂] up to ~440 GHz [3], which corresponds to a length scale of ~10 nm. This result might thus suggest that the low-temperature thermal properties of glasses should mimic those of their crystalline counterparts, at least below 2–3 K, but this does not seem to be generally the case. From the expected non-plane-wave character of the high-frequency eigenmodes, it is further anticipated

that selection rules should be relaxed in spectroscopic studies, complicating the analysis and limiting the amount of information that can be obtained from vibrational spectra.

3 Vibrations and Thermal Properties

3.1 Heat Capacity

The heat capacity $C_v \approx C_p$ of a perfect crystal obeys Debye law $C_p(T) = C_D T$ at temperatures below $\sim 0.01 \theta_D$, where θ_D is the Debye temperature and $C_D \propto \theta_D^{-3}$ can be calculated from the sound velocities and the atomic density. At higher temperatures, C_p begins to probe the details of the atomic structure via the acoustic dispersion curves throughout the Brillouin zone and eventually the optic modes.

The measured heat capacity of α -quartz nicely illustrates this point. Below 5 K, C_p/T^3 almost perfectly matches the expected Debye value whereas the upturn above 10 K is fully described by the curvature of the acoustic phonon branches. In α -cristobalite, the SiO₂ polymorph whose density is close to that of the glass, C_p/T^3 reaches its constant Debye value only below 2 K, in agreement with its lower atomic density. Giving rise to a large bump around 13 K, the very steep increase at higher temperature is mostly related to the rapid flattening of the transverse acoustic branches in the $\langle 110 \rangle$ direction [4, 5]. Because a given vibrational mode contributes to the heat capacity according to its relative weight in the vibrational density of states, the intense Raman active zone center mode of α -cristobalite around 50 cm⁻¹ [6], for example, enhances C_p from 15 K, just above the maximum of C_p/T^3 .

In contrast, the heat capacity of ν -SiO₂ does not conform to Debye model. Its larger value at 2 K indicates extra modes at low frequencies. Close to 0 K, part of this excess is due to an almost linear contribution proportional to temperature, which is associated with tunneling states [7–9], whose discussion is beyond the scope of this chapter. Subtracting this feature (Figure 2a) still leaves an excess over the Debye prediction. In agreement with their analogous local order and atomic packing, ν -SiO₂ and cristobalite display similar peaks in $C_p(T)/T^3$ and reduced density of states $g(\Omega)/\Omega^2$. Such common features early indicated [4] that low-energy peaks are not a peculiarity of glasses [10, 11] although they do not necessarily imply a common origin for both kinds of phases. The heat capacity of cristobalite is, for instance, completely understood in terms of phonon-branch dispersion. In contrast, the linear dispersion of sound waves up to at least 440 GHz [3] in ν -SiO₂ gives a constant Debye value up to ~5.5 K (dashed line in Figure 2a) which is inconsistent

Figure 2 Low-temperature thermal properties of SiO₂ phases. (a) Low-temperature heat capacity of vitreous silica, α -cristobalite, and α -quartz in plots of C_p/T^3 against T . Horizontal lines: Debye constants (dashed, dotted, and full line, respectively). Open circles: C_p/T^3 of vitreous silica without the two-level system contribution. (b) Thermal conductivity of the same polymorphs. Inset: frequency dependence of the mean free path in vitreous silica in the dominant-phonon approximation.

with both the position and width of the peak in $C_p(T)/T^3$. One must assume instead a $g(\Omega) \propto \Omega^4$ relationship on top of the Debye contribution [7]. Such an Ω^4 dependence of the density of states is an ubiquitous feature in disordered systems [12]. But whether the excess above the Debye expectation at temperature below the maximum in C_p/T^3 (shaded area in Figure 2a) is a manifestation of disorder and, as such, is related to a strong scattering of the acoustic phonons in glasses occurring at high frequencies is a central and still unsettled question. Only these vibrational excitations define the *boson-peak modes*, as will be further discussed in Section 6.

3.2 Thermal Conductivity

In dielectric crystals, significant scattering of acoustic phonons is reflected in the low-temperature thermal conductivity κ . With the standard kinetic equation for gases, one approximately describes the temperature dependence of κ by

$$\kappa = \frac{1}{3} C_v \nu l, \quad (4)$$

where C_v is the heat capacity per volume of the excitations providing the thermal transport, ν their velocity of propagation, and l their mean free path [13]. This expression is obviously valid only for propagating phonons, i.e. below 1–2 THz in glasses as discussed below in the same subsection. From ambient, κ increases with decreasing temperature through the increasing lifetimes of acoustic excitations. As there are fewer and fewer phonons, l increases as T^{-1} at high temperatures. The mean free path is of course limited by sample dimensions so that κ goes through a maximum, the *Casimir limit*, and then

decreases with the T^3 dependence of C_v at low temperatures as illustrated by the thermal conductivity of α -quartz along the c -axis (Figure 2b).

By contrast, the thermal conductivity of a dielectric glass material is much lower and has a markedly different temperature dependence. These features are illustrated by vitreous silica (Figure 2b) for which κ increases non-monotonously with increasing temperature with a remarkable plateau beginning just below the hump in C_p/T^3 . At very low temperatures, κ follows an approximate T^2 law instead of the T^3 dependence expected from the Debye approximation. According to a widely accepted interpretation, this initial T^2 rise is due to interactions between phonons and tunneling states, which reduce l in glasses [7–9].

The microscopic origin of the plateau around 3–15 K is in contrast a much more controversial issue. In early calculations, a very efficient phonon-scattering mechanism was assumed by a proportionality of l to at least Ω^{-4} [14], which suggested Rayleigh scattering from disorder in the glassy network. From Eq. (4), it is possible to estimate a mean value for $l(T)$ that can be recast in $l(\Omega)$ with the dominant phonon approximation $\hbar\Omega \sim 3.8 k_B T$ (Figure 2b). In the hypersound frequency range, i.e. below 100 GHz, $l(\omega)$ exceeds 1 μm so that it is much larger than the acoustic wavelength λ , confirming the assumption of propagation. In this range, resonant relaxation by tunneling states dominates acoustic attenuation below 1 K (Figure 2b, top x scale), yielding $l(\Omega) \propto \Omega^{-1}$. Above about 100 GHz, $l(\Omega)$ drops rapidly following an approximate Ω^{-4} trend. Near 1 THz, it becomes comparable to the acoustic wavelength λ , marking the Ioffe-Regel crossover from propagating plane-wave acoustic modes to diffuse excitations. Above the corresponding frequency Ω_{IR} , the wave vector loses

its meaning and the notion of phonon becomes ill-defined. Sound waves do not propagate and can no longer transfer energy. The dominant phonon approximation certainly breaks down as well in this range. Only recently has this frequency region become available for coherent spectroscopy of acoustic phonons. At higher temperatures, κ rises again and eventually saturates at around 1 W/m/K. As heat transport can no longer be mediated by propagating sound waves, it is generally admitted that κ is governed here by diffusion mechanisms [15, 16].

Finally, the room-temperature conductivity of α -cristobalite of ~ 6 W/m/K (Figure 2b) is close to the value obtained in the direction normal to the c -axis in α -quartz and much higher than the ~ 1 W/m/K reported for ν -SiO₂. This feature suggests that the temperature dependence of the thermal conductivity of α -cristobalite is essentially governed by anharmonic processes and follows the expected crystalline increase up to the Casimir limit when the temperature is lowered. Hence, the very rapid flattening of the dispersion curves of the acoustic branches in the $\langle 110 \rangle$ direction, which causes the hump in C_p/T^3 , is by no mean sufficient in itself to produce a plateau in κ around 10 K.

4 Inelastic Spectroscopy in Glasses

4.1 Dispersion Diagram and Experimental Techniques

The dispersion curves of the longitudinal phonons of vitreous silica and amorphous selenium, in the region where

they are plane waves, illustrate the variety of techniques used to study atomic excitations in disordered systems (Figure 3). The frequency range of network optic modes (typically between a few THz and ~ 2000 THz) is delineated by horizontal dashed lines whereas the boson peak stands on the low-frequency limit of that region (~ 0.5 – 3 THz). The longitudinal acoustic branch of vitreous silica has, for instance, been widely investigated by inelastic X-ray scattering (IXS), whereas ν -Se is one of the few examples where longitudinal sound velocity is sufficiently low to be accessible by inelastic neutron scattering (INS).

Depending on their frequency and scattering wave vector, some of the techniques displayed in Figure 3 are sensitive to relaxation only (X-ray photon correlation spectroscopy [XPCS], photon correlation spectroscopy [PCS], and neutron spin echo [NSE]), others to both relaxation and vibrations (ultrasonics [US], Brillouin light scattering [BLS], picosecond optical technique [POT], Raman scattering [RS], IXS, INS, and neutron backscattering [NBS]) whereas the scattering vector $\mathbf{q}$ is not defined for infrared absorption (IR) and US, which do not involve scattering. Much of the dispersion diagram is nowadays experimentally accessible except in the domain between 10^{-1} and $\sim 2 \times 10^{-3} \text{ \AA}^{-1}$ located at the limit of the Ioffe-Regel crossover region, defined by q_{IR} (Section 5.2). Owing to kinematic conditions, INS is not a technique of choice for such experiments, at least in structural glasses of rather high sound velocities. Close to $q = 0$, it is of course not possible to measure sound waves whose velocities are larger than those of the incident neutrons. Accordingly, the high-frequency limit of INS in Figure 3 roughly corresponds to the highest

Figure 3 Dispersion of longitudinal acoustic phonons in vitreous silica ($v_{\text{LA}} = 5960$ m/s) and selenium ($v_{\text{LA}} \cong 1800$ m/s) and relevant ranges of the scattering techniques probing atomic excitations in disordered materials: ultrasonics (US), Brillouin light scattering (BLS), Raman scattering (RS), picosecond optical technique (POT), infrared absorption (IR), inelastic neutron scattering (INS), inelastic X-ray scattering (IXS), neutron spin echo (NSE), neutron backscattering (NBS), photon correlation spectroscopy (PCS), and X-ray photon correlation spectroscopy (XPCS). The frequency domain of optic vibrations in network glasses is delineated by horizontal dashed lines.

neutron velocities enabling measurements down to $q \sim 0.1 \text{ \AA}^{-1}$. Another drawback of INS and IXS is their inability to probe transverse acoustic phonons close to $q = 0$.

4.2 Scattering Intensity

The intensity $I(\mathbf{q}, \omega)$ of an incident radiation scattered by a material is proportional to the space and time Fourier transform of the correlation function of the physical quantity (let us call it A), which couples to the incoming radiation [17]:

$$I(\mathbf{q}, \omega) \propto FT \left\{ \int_V \int_t A(\mathbf{r}, t) A(\mathbf{r} + \mathbf{r}', t + t') dt d\mathbf{r} \right\} \quad (5)$$

$$= C(A) \cdot S(\mathbf{q}, \omega).$$

For X-ray, neutron, and light scattering, A stands for the electronic density ρ_e , the coherence length b , and the dielectric susceptibility χ , respectively, and the function $C(A)$ expresses the selection rules of the scattering experiment. It depends on the strength of the coupling of the incident radiation to a vibration and, therefore, modulates the intensity of its spectral shape given by $S(\mathbf{q}, \omega)$. For light scattering, the susceptibility χ can be expressed in terms of the polarizability tensor $\bar{\alpha}$, the hyper-polarizability tensor $\bar{\beta}$, or the photo-elastic tensor $\bar{p}$, giving rise to Raman, hyper-Raman, and Brillouin processes. Neutron scattering is sensitive to all vibrations and enable measuring the phonon dispersion curves over a large $(\mathbf{q}, \omega)$ range. The vibrational density of states is given by the normalized integral over all $\mathbf{q}$ -values and yields $g(\omega)$. In neutron scattering studies, however, the latter is modulated by the coherent length of the atoms so that it remains an approximate quantity.

However, structural disorder prevents a general theory from being formulated to describe vibrational selection rules hidden in the expression of $C(A)$ in glasses, analogous to the role of group theory played for crystals and molecules. This is one of the main reasons why the description of atomic vibrations is hardly accessible. Another limitation is the spatial localization of the modes described in Section 4.3.

4.3 Coherent and Incoherent Scattering

In disordered media, a very important consequence of the spatial localization of extended waves is a loss of coherence of the scattering process due to the ill-defined nature of the wave vector $\mathbf{Q}$ of the vibration. But the momentum keeps conserved when modes are characterized by a

spatial extension larger than the probed wavelength, e.g. acoustic and optic phonons in crystals

$$\mathbf{Q} = \mathbf{q} = \pm (\mathbf{k}_i - \mathbf{k}_s). \quad (6)$$

Only the vibrations whose wave vectors $\mathbf{Q}$ match those of the experiments $\mathbf{q} = \pm(\mathbf{k}_i - \mathbf{k}_s)$ will then be active for a given scattering geometry. Hence, one observes that understanding selection rules requires to distinguish the frequency and wave vector of the vibration $(\Omega, \mathbf{Q})$ from that accessible by the instrument $(\omega, \mathbf{q})$.

The other extreme situation corresponds to non-propagating vibrations of fully localized molecular motions as observed in liquids or gases. A perfect localization in real space leads to an infinite spectral broadening of Q , $\Delta Q \rightarrow \infty$, in the Fourier space. Hence, $\mathbf{Q}$ is not a relevant physical quantity and the vibration scatters at every $\mathbf{q}$ value.

For the intermediate situation of quasi-localized vibrations, the coherence length of the mode – if it is sufficiently short – may induce a wave vector spectral broadening ΔQ (horizontal lines in Figure 1a). In that case, *the contribution at ω in the vibrational spectrum is the sum over all modes of frequency $\Omega = \omega$ having a wavevector spectral component Q matching the scattering wave-vector q of the experiment.* The above conclusion holds true in glasses for optic modes as well as for short-wavelength acoustic waves since the latter progressively transform into quasi-localized vibrating entities at high frequencies (cf. Section 2).

Another way to address the propagation of acoustic phonons in amorphous solids is to consider plane waves propagating in a mechanically inhomogeneous medium [18] where χ depends on position. The disorder induces a spatial modulation of the photoelastic constants, resulting in distorted acoustic waves whose coherence length is limited by local elastic inhomogeneities, as in the model developed in Section 2. A full treatment shows that the light-scattering spectrum consists of the usual Brillouin peaks and a background rising as ω^2 originating from the incoherent contribution induced by these local heterogeneities.

5 Vibrational Spectra

5.1 Optic Modes in the Glass Formers SiO_2 and B_2O_3

Incoherent scattering process combines with structural disorder to produce broad bands in the Raman and infrared spectra. If the glass has a short-range structure similar to that of a crystalline counterpart, its vibrational spectrum will generally represent a smeared-out version of that of the crystal. For example, the similarities

between vitreous silica and its crystalline counterparts are striking (Figure 4).

The lack of long-range order prevents vibrations in glasses from being described in a unique way. A first possibility is to consider the atomic displacements (eigenmodes) of an elementary structural unit such as the

Figure 4 Raman spectra of ν -SiO₂, α -quartz, and polycrystalline α -cristobalite.

SiO₄ tetrahedron of T_d -symmetry or the Si–O–Si bridge of C_{2v} -symmetry in ν -SiO₂, and the BO₃ triangle of D_{3h} -symmetry or the B–O–B bridge in ν -B₂O₃. A second possibility is to define rocking, bending, and stretching motions of N–O–N units, where N=Si, B, Ge, etc. A pure bending modulates only the N–O–N bond angle whereas a pure stretching modifies the N–O bond length. Finally, numerical simulations often project displacements over three orthogonal axes also defined as bending, stretching, and rocking axes. The first one is perpendicular to the N–O–N plane, the second is parallel to the N–O–N bisector, and the third is parallel to the N–N direction. In that case, bending and stretching are not pure vibrational modes. These definitions are not unequivocal, however, so that they can foster confusion in mode assignments. Owing to network connectivity, the spectral responses generally involve several structural units, which further complicates the description. Although some of the conclusions are still discussed, atomic displacements are tentatively summarized hereafter for the main glass formers.

For ν -SiO₂ and ν -B₂O₃, the differences between the IR, Raman, and hyper-Raman spectra (Figures 5 and 6) indicate that selection rules do apply in glasses with sufficiently well-defined local structures. The three polar modes TO1, TO2, and TO3 in ν -SiO₂ are, for example,

Figure 5 Vibrational spectroscopy of ν -SiO₂ and atomic displacements for the main modes [19–21]. From top to bottom: infrared absorption, hyper-Raman scattering, Raman scattering, and vibrational density of states derived from neutron scattering [22]. N.B. F_1 vibrations seen in HRS are not the only ones participating in the boson peak.

Figure 6 Vibrational spectroscopy of ν -B₂O₃ and atomic displacements for the main modes [19–21]. N.B.: F_1 vibrations seen in HRS are not the only ones participating in the boson peak.

active in IR, Raman, and hyper-Raman, in agreement with either the C_{2v} - or T_d -symmetry selection rules. Within the T_d point group, F_2 -symmetry stretching motions of SiO₄ tetrahedra (F_{2s}) contribute preferentially to TO1 and TO2, whereas F_2 -symmetry bending ones (F_{2b}) dominate in TO3 [20]. Since the Raman inactivity of TO4 cannot be accounted for by any of the internal vibrations proposed by the two structural models, this mode rather represents highly cooperative motions involving rocking of the oxygen atoms [21, 23] in the Si–O–Si bridges the weak value of the depolarization ratio (I_{VH}/I_{VV}) of the Raman R , D_1 , and D_2 bands are compatible with A_1 -bending of the Si–O–Si bridges of C_{2v} -symmetry. The displacements are in phase in the three- and four-membered ring (Si–O–Si)_{*n*} planar structures ($n = 3$ and 4 , respectively), and are commonly ascribed to breathing modes. Such motions induce very weak dipolar fluctuations and are, therefore, almost inactive in IR and hyper-Raman scattering (HRS). Likewise, in the vibrational spectrum of ν -B₂O₃ (Figure 6), the atomic displacements proposed are compatible with the molecular selection rules of the D_{3h} -symmetry group of BO₃ triangles and B₃O₆ boroxol rings.

Although very powerful, vibrational techniques do not lend themselves to quantitative structural estimates. Even though numerical simulations are proving valuable in this respect, thanks to calculations of the coupling-to-light coefficients $C(A)$ in Eq. (5) or to NMR calibrations, the main asset of inelastic spectroscopies remains their ability to derive information that may be difficult or even impossible to obtain with conventional structural techniques. For example, three- and four-membered rings represent only one per 670 and 550 SiO₂ units, respectively [24]. These proportions are much too low to be detected in a diffraction experiment, but high enough to produce the narrow D_1 and D_2 Raman bands. Whereas the broad R -band probes the Si–O–Si angle distribution [22, 25], the high-frequency feature depends on the fraction of Q^n -species in binary or more complex silicates. The role of modifier, charge compensator, or glass former played by other cations can also be investigated. In ν -B₂O₃, structural information accessible by vibrational techniques concerns, for instance, the fraction of boroxol rings B₃O₆ and the ratio of BO₃-triangles and BO₄-tetrahedra in binary glasses (Chapters 2.8 and 7.6).

5.2 Acoustic Excitations

At large wavelength, i.e. in the continuum limit, acoustic waves propagate in glasses as they do in crystals. Almost nondispersive sound waves have been indeed measured at low frequencies with ultrasonic (MHz) Brillouin scattering (GHz) or picosecond optical pump-and-probe (100 GHz) experiments. At these frequencies, quasi-plane waves do propagate but with higher attenuation rates than generally found in crystalline solids. The anharmonicity of thermal atomic vibrations causes the attenuation of sound waves in crystals [26] and is in addition reflected in the temperature dependence of the sound velocities or in thermal expansion. The same mechanism is also present in glasses, but it coexists with other damping processes that are mostly specific to them.

At low frequencies, the energy mean free path of acoustic phonons is limited by resonant interactions with tunneling states at low temperatures and by thermally activated relaxation at higher temperatures, both leading to $l^{-1} \propto \omega$ (Figure 7a). The latter mechanism is empirically described by the relaxation of group of atoms or “defects” between two or more equilibrium positions [27, 28]. At hypersonic frequencies, anharmonic processes coexist with thermally activated relaxation to drive a smooth transition from a $l^{-1} \propto \omega$ law to a $l^{-1} \propto \omega^2$ trend from low to high temperatures as clearly observed above GHz frequencies (Figure 7a).

The combination of these mechanisms thus results in complex variations of $l^{-1}(\omega, T)$, which strongly depend on glass composition. Finally, very short-wavelength sound waves experience a disorder-induced strong scattering regime, which dominates above 0.1–0.2 THz, depending on temperature and on the efficiency of the other damping mechanisms. The dramatic increase of $l^{-1}(\omega)$ rapidly produces the Ioffe-Regel crossover at the frequency $\omega_{\text{IR}}/2\pi$ (Figure 7a). Such a rapid decrease of the mean free path is actually the trend required to produce the aforementioned plateau in $\kappa(T)$ around 10 K.

With techniques ranging from Brillouin to IXS, it has become possible to study longitudinal acoustic excitations just below the IR crossover. In two favorable cases [29, 30], detailed measurements have revealed the existence of a very rapid increase of the Brillouin linewidth $\Gamma = l^{-1}v_L$, where v_L is the longitudinal sound velocity as illustrated by lithium diborate glass $[\text{Li}_2\text{O} \cdot 2\text{B}_2\text{O}_3]$ at 573 K (Figure 7b, inset). In the Brillouin spectrum taken at the smallest usable Q , the fitted elastic peaks have been subtracted from both the data and the fit to make the inelastic parts and their damped harmonic oscillator components apparent. At this low- q value, the Brillouin width is almost entirely instrumental, whereas it contains a real and large broadening in the bottom inset. At that point, the lineshape of the damped harmonic oscillator begins

Figure 7 Inverse mean free path $l^{-1}(\omega, T)$ of longitudinal acoustic excitations in glasses. (a) For $v\text{-SiO}_2$: curves calculated with four damping mechanisms, namely, interactions with tunneling states, thermally activated relaxation, anharmonicity, and Rayleigh scattering at high frequency, which leads to the Ioffe-Regel crossover at ~ 1 THz (star). (b) For lithium diborate glass as measured at 573 K with BLS (green squares) and IXS (filled triangles). Dotted lines referred to the different damping processes: thermally activated relaxation plus lithium diffusion at GHz frequencies, anharmonicity around 0.5 THz, and Rayleigh scattering at THz frequencies. IR crossover at ~ 2.4 THz (star). Inset: dramatic increase of the Brillouin linewidth in IXS spectra in the IR crossover between $q = 1.1$ and 2.4 nm^{-1} .

to deviate increasingly from the measured signal. The reciprocal of the energy mean free path corresponding to the Brillouin linewidths from all the measured IXS spectra is reported in the main graph of Figure 7b.

Following a ω^4 trend, the dramatic increase of l^{-1} is clearly evidenced over a decade. At $q = q_{\text{IR}} = 2.4 \text{ nm}^{-1}$, the Brillouin linewidth reaches one-third of the Brillouin frequency, which is the Ioffe-Regel criterion. The IXS spectra measured at higher q values are inconsistent with a single damped-harmonic oscillator response, demonstrating that this approximation is no longer valid, thus marking the end of acoustic plane waves at q_{IR} in this glass. In Brillouin light-scattering experiments made at the same temperature (Figure 7b), the l^{-1} values obtained also show that damping in this (ω, T) region is dominated by thermally activated relaxation processes and lithium diffusion, leading to an approximate $l^{-1} \propto \omega$ dependence, in agreement with ultrasonic experiments. From the temperature variation of the sound velocity, an estimate of the anharmonicity contribution at 573 K ($l_{\text{anh}}^{-1} \propto \omega^2$ in Figure 7b) shows that this mechanism should dominate in a narrow frequency range around the crossover between ω^1 and ω^4 trends. More recently, similar IXS measurements made on ν -SiO₂ and glycerol [C₃H₈O₃] have also indicated such a dramatic increase of the reciprocal of the mean free path of longitudinal acoustic excitations at THz frequencies.

The results obtained for a densified ν -SiO₂ and then on lithium diborate glass have represented the first experimental evidence for the existence of a Rayleigh-type scattering mechanism of acoustic phonons in glasses producing an Ioffe-Regel crossover at some large acoustic wavelengths. The observation of both phenomena firmly demonstrated that the plane-wave approximation has already lost all validity at an intermediate scale, i.e. at about 1–3 nm depending on the glass. The observed crossover from propagating to diffusing sound waves has also offered a natural explanation for the anomalous low-temperature plateau in thermal conductivity. In several glasses investigated so far, ω_{IR} is close to the boson-peak frequency ω_{BP} , suggesting a direct relationship between both quantities. The correspondence is not one to one, however, as ω_{IR} remains at or above ω_{BP} . It is believed that the boson-peak frequency actually corresponds to the Ioffe-Regel crossover frequency for the transverse acoustic excitations in all glasses, but no experimental data have demonstrated the validity of this statement yet.

6 The Boson Peak

The excess of vibrational modes in the reduced vibrational density of states $g(\omega)/\omega^2$ translates into a broad and asymmetric band at frequencies between 0.5 and 3

THz in Raman or infrared spectra, corresponding approximately to the end of the acoustic branches. Vibrations of different origins are likely participating in that frequency region and should be separated into glass-specific vibrations (*boson-peak modes*) and crystalline-like vibrations (*non-boson-peak modes*). Many attempts have been made to relate the boson peak, e.g. to the medium-range order [31], the crystalline phases [11], or the macroscopic properties [32]. This section will focus on the origin of the vibrations underlying this excess of modes.

6.1 Oxide Glasses

In quartz, a very important vibration is the soft mode associated with the structural α – β instability at 846 K whose displacements have been interpreted as librations of SiO₄ tetrahedra. Its temperature dependence has been measured by neutron scattering (Figure 8b) and its frequency extrapolates to $\sim 36 \text{ cm}^{-1}$ at $T_g \sim 1600 \text{ K}$, i.e. to the frequency of the maximum of $g(\omega)/\omega^2$ measured by INS (Figure 8c). Librations of rigid units are also soft

Figure 8 Vibrational excitations in ν -SiO₂. (a) Dispersion curve of acoustic modes and low-lying optic branches along the $\Gamma \rightarrow M$ (plain lines) and $\Gamma \rightarrow Z$ (dot dashed lines) directions of the Brillouin zone; squares Raman data. (b) Raman spectra of α -cristobalite and neutron spectra of the soft mode of β -quartz at 1250 K whose position at T_g is indicated by the dashed line at around 36 cm^{-1} . (c) Spectroscopic signatures of the boson peak; possible vibrational contributions indicated by shadowed regions and the vertical dashed lines.

vibrations in β -cristobalite but are located at the zone boundary of a transverse acoustic branch. These low-frequency excitations have been identified as *rigid unit modes* [33], i.e. external modes combining librations and translations of rigid elementary units. These units associate with weak interunit restoring forces in the glass and therefore vibrate at low frequency.

Similarly, INS, hyper-Raman, as well as numerical simulations have highlighted the presence of librations of rigid SiO_4 (F_1 -symmetry displacements in Figure 5) at boson-peak frequencies in vitreous silica [34, 35]. Librations also participate at boson-peak frequencies in pure boron oxide (Figure 6) but with a lower weight than in ν - SiO_2 . In this respect, silica is probably a peculiar system since librations are soft modes of the crystalline polymorphs, which to our knowledge is not the case for boron oxide. In connected networks, librations couple with translations of rigid units and hybridize with transverse and longitudinal acoustic phonons of similar frequency. This source of scattering combines with the strong scattering process of sound waves close to the Ioffe-Regel crossover frequency (shadowed regions in Figure 8a–c) to build up the reservoir of *boson-peak modes*. The loss of the Brillouin zone combined with the localization of the plane waves in the glass makes identification of these vibrations as acoustic- or optic-like useless. Owing to the different nature of these modes, the boson peak manifests itself in a way specific to the spectroscopic technique used, leading to differences in neutron, Raman, hyper-Raman, and infrared responses. What matters first and foremost is that these excitations relate to the structural disorder of the glass and to the plateau of the thermal conductivity.

Crystalline-like modes may also contribute at frequencies beyond that of the boson peak such as the Raman modes at ~ 50 and $\sim 120 \text{ cm}^{-1}$ in α -cristobalite (Figure 8b) [36] or cation modes in soda-lime-silicate glasses [37]. Indeed, the vibrational density of states $g(\omega)$ of ν - SiO_2 below 300 cm^{-1} (as well as its Raman spectra) is very complex, pointing to numerous low-frequency optic vibrations (Figure 5). Conversely, that of B_2O_3 looks like Van-Hove singularities of transverse and longitudinal acoustic branches (Figure 6) emphasizing thereby a much weaker contribution from *crystalline-like* optic modes.

6.2 Other Glasses

The picture is even more complicated in molecular glasses (e.g. glycerol, ortho-terphenyl) where a large number of intramolecular and reorientational motions are likely to contribute at low frequency, leading to a great complexity in both vibrational responses and structural relaxation (Chapter 8.6). Hence, these systems generally do not represent good model systems for studying the boson peak.

Metallic glasses may in contrast prove useful in this respect. The simplest ones can be usually described as chemically and positionally disordered dense-packed structures without orientational interactions or intramolecular processes (Chapter 7.10). Consistent with the Lennard-Jones interacting-sphere model, the excess of low-frequency modes in C_p between ~ 10 and 30 K is then often composed of purely harmonic vibrations, i.e. of Einstein modes corresponding to local excitations of loose atoms in the glassy structure. Unfortunately, electronic and atomic properties often mix in metallic glasses, which may confuse the description of the boson peak and thermal properties. Electronic processes at impurity sites may, for example, contribute to localized excitations at boson-peak frequencies whereas thermal conductivity may also be dominated by electronic heat-transfer channels, which are much more efficient than atomic ones in conductors.

In the large family of non-insulating glasses, amorphous silicon (a -Si) is probably one of the simplest examples. Its crystalline counterpart (c -Si) has only one triply degenerate optic mode at $\omega = 520 \text{ cm}^{-1}$, which leads to an interesting situation where only acoustic branches contribute to the vibrational density of states below $\sim 350 \text{ cm}^{-1}$ (Figure 9a). The crystalline tetrahedral short-range order is preserved in the glassy state so that the densities of the two forms differ by 1.8% only. This structural similarity lends support to qualitative comparisons between vibrational properties. For example, the vibrational densities of states are similar below $\sim 350 \text{ cm}^{-1}$ with only a downshift of the band maxima in the glass, reflecting lower sound velocities (Figure 9b). Despite the absence of optic modes at low frequency, the Raman spectrum is not flat but displays broad structures that have been associated with both second-order processes on acoustic branches [38, 39] and disorder-induced scattering due to acoustic plane-wave destruction (Sections 2 and 5.2). The latter effect seems to be rather weak in a -Si, however, since it yields a moderate damping mechanism of the acoustic phonon branches, proportional to q^2 [16, 40], as compared with the very fast q^4 -law observed in network glasses. This probably explains why the Raman response is very similar to the $g(\omega)$ measured by INS (Figure 9b) [41].

As in crystalline silicon, C_p/T in a -Si varies without showing evidence for two-level systems at least down to 2 K [4, 42]. The weak damping regime of the acoustic phonons goes against the formation of a plateau in the thermal conductivity as well. Unfortunately, however, existing reports are controversial and firm experimental evidence is still lacking on that question. Finally, the Ioffe-Regel crossover frequency is upshifted toward the end of the transverse acoustic branch (Figure 9b) [16], which raises some doubts about its physical meaning.

Figure 9 Vibrational excitations in crystalline and amorphous silicon. (a) Dispersion curves along the X (symbols and lines) and L (dot-dashed lines) directions of the crystal [38]; dispersion curves of acoustic phonons about 25% lower in the glass than in the crystal. (b) Vibrational density of states $g(\omega)$ (thin lines) [41] and Raman scattering spectra (bold lines) of amorphous silicon [37] and c-Si. Plane wave, boson-peak mode, and ω_{IR} transverse and longitudinal acoustic limits taken from [16].

In the current state of knowledge, the only reliable glass-specific vibrational feature of amorphous silicon is, therefore, the partial destruction of acoustic plane waves at large q (i.e. short wavelengths). Although moderate, this mechanism generates *boson-peak modes* at frequencies between the plane-wave regime and the Ioffe-Regel crossover at ω_{IR} .

7 Perspectives

Inelastic scattering selection rules in glasses are relaxed by local structural and mechanical disorder, yielding broad and asymmetric spectral responses. Unlike for crystals, there exists no well-established analytical theory of the atomic displacements that underlie the spectral responses. Analyses remain mostly phenomenological, except perhaps for simple glasses for which atomistic simulations nowadays provide a firmer theoretical foundation. Indeed, the nature of the vibrations in the main oxide glass formers, up to binary and to a lesser extent ternary systems, is relatively well understood. Extracting quantitative structural information, in particular from RS, remains a challenging issue.

Even more challenging is the nature of the boson peak. Its modes participate at low frequency in the vibrational

spectra of most disordered systems. These vibrating entities mostly originate from a renormalization and a redistribution of the modes of the acoustic branches due to the destruction of plane waves of nanometer wavelengths. They can eventually hybridize with low-lying optic vibrations (rigid-unit modes), such as the librations of rigid SiO_4 tetrahedra in silica or loose local atomic motion in Lennard-Jones-type metallic glasses. The purely acoustic-type damping mechanism, enhanced by the second one when relevant, induces a very fast decay of the mean free path of the acoustic phonons at THz frequency, as evidenced by IXS and numerical simulations. There follows a crossover from a propagative to a diffusive character of sound waves and offers a natural explanation of the low-temperature plateau of thermal conductivity.

These modes build up the boson-peak structure mostly below its maximum in $g(\omega)/\omega^2$ plots in Raman and INS spectra. At higher frequencies, this spectral response mixes with those of other mechanisms, such as incoherent scattering from high-frequency acoustic branches due to the loss of wave vector selection rules, direct scattering of low-lying optic branches, second- or higher-order RS processes, and possibly others. It is tempting to define the boson peak as arising from the sum of all the excitations that construct the broad feature at THz frequency in glass, as it is often done in literature. Here, we have

preferred to separate the *boson-peak modes* from the other scattering processes since the latter are related to spectroscopic considerations whereas the former accounts for solid-state properties specific to glasses. Current advances in numerical simulations have allowed the boson-peak modes at the origin of the plateau in κ to be identified in very few cases [16, 43]. Highlighting them over the other scattering channels in a scattering experiment probably constitutes one of the most challenging issues of the coming decades.

3.5

Density of Amorphous Oxides

Michael J. Toplis

Institut de Recherche en Astrophysique et Planétologie, Observatoire Midi Pyrénées, Université de Toulouse, Toulouse, France

1 Introduction

Density is a fundamental thermodynamic property, an essential characteristic of any condensed phase and one that is readily measured with great accuracy. The density of glassy and/or molten oxides is also of significant practical interest in a wide range of industrial and geological contexts. In the glassmaking and metallurgical industries, the difference in density between molten silicates and metals is the key to successful manufacture of everyday products such as float glass used in the construction and automobile industries, whereas, farther from home, the density of magmatic silicate liquids controls the time-scales of movement and the spatial distribution of crystals within the interiors of the Earth, Moon, and Mars.

In a little more detail, the density of amorphous oxides is a function of composition, temperature, and pressure. In the liquid state, temperature and/or compositional gradients can thus lead to density differences that are capable of driving material transport (i.e. convection), leading to mixing that may or may not be favorable for a given application. This link between large-scale material transport and liquid density highlights the critical importance of derivative properties such as thermal expansivity.

Temperature-dependent changes in density are also particularly critical when cooling a liquid across the glass transition. If the need to anneal a glass before cooling it down to room temperature has been known from time immemorial, it was understood only in the nineteenth century that the internal stresses to be eliminated in this

way originated from small changes in the local cooling rate throughout the glass piece (Chapter 3.7). Conversely, it was then realized that controlled generation of high local compressive stresses either by thermal or chemical means could be used to strengthen glass (Chapters 3.7 and 3.12). In the glassy state density continues to play a role, having an effect on optical properties such as refractive index and sound wave propagation. For example, chemical heterogeneities result in density differences that cause deformation of the optical path, a phenomenon generally observed in window panes produced before the float process was designed (Chapter 1.3).

Further to these general considerations, it must not be forgotten that the pressure dependence of the Gibbs free energy of a phase of constant composition is simply the volume. In other words, liquid volume (and thus density) has a direct influence on free energy and thus on phase equilibria, in particular on the variation of melting temperature as a function of pressure. One obvious application of this fact is that high-pressure melting of planetary interiors is critically sensitive to liquid volume and its pressure derivative, compressibility.

This brief introduction highlights a few of the implications of the density of amorphous materials. In the following, we will focus on a more detailed assessment of how volume is measured both at high and low temperature; how densities vary as a function of composition, temperature, and pressure; and how future work may lead to new breakthroughs in understanding variations in volume and/or result in novel practical applications. In addition to volume (V), the properties of interest here are the thermal expansivity $(\partial V/\partial T)_P$ and the isobaric thermal expansion coefficient $\alpha = 1/V(\partial V/\partial T)_P$ along with the isothermal and adiabatic compressibilities, $\beta_T = -1/V(\partial V/\partial P)_T$ and $\beta_s = -1/V(\partial V/\partial P)_S$, respectively.

2 Measuring the Density of Amorphous Oxides

2.1 Theoretical Considerations

For a homogeneous liquid in internal thermodynamic equilibrium, the volume is uniquely defined at a given pressure and temperature (Figure 1). This also applies to the supercooled liquid state in the absence of crystals as long as the experimental timescale is longer than the structural relaxation time (Chapter 3.12). Because structural relaxation is a thermally activated process, with a more or less exponential temperature dependence, the transition from a fully relaxed liquid in internal equilibrium to an amorphous material whose structure is fixed (i.e. a glass) typically occurs over a restricted temperature range upon cooling.

This kinetic origin of the liquid-to-glass transition has the consequence that the temperature at which internal equilibrium of the liquid can no longer be maintained depends on cooling rate. Because the thermal expansion coefficient markedly decreases from the liquid to the glass state, the volume/density of a glass cannot be calculated from pressure, temperature, and composition alone, but also requires knowledge of the temperature–time path during cooling. Put another way, glass chips of the same composition can have different densities if they have been cooled at different rates (Chapters 3.8 and 10.11).

Figure 1 Volume variations in the glass transition range: contrast between the uniquely defined value of the supercooled liquid and the cooling-rate-dependent values of the glass. Limiting fictive temperature defined by the intersection of the extrapolated glass and liquid curves. Volume changes toward the equilibrium value associated with structural relaxation indicated by the thin dashed lines (after [1]).

2.2 Density of Amorphous Solids

Some of the earliest attempts to measure the density of amorphous oxides systematically were developed by the glassmaking industry well over 100 years ago with a simple but efficient technique with which a glass bead is immersed in a liquid whose temperature is varied until its point of neutral buoyancy is reached. If the density of the liquid is known as a function of temperature, then that of glass may be determined to better than 0.05%. Whereas this technique is well suited for extremely precise measurements of a sample whose density is approximately known, it is far less practical for an unknown sample since a given reference liquid only covers a small range of density.

For this reason, alternative methods have been developed, also typically based on Archimedes' principle, which states that a solid body immersed in a fluid is buoyed up by a force equal to the weight of the fluid displaced by the body. One may apply this principle to measure the density of amorphous solids (ρ_s) by weighing a glass chip in air and in a fluid of known density (ρ_l), such as toluene. The weight in air provides a measurement of the mass of the chip, whereas the difference between the weight in air and in the fluid is used to calculate the volume of the chip with

$$\rho_s = \frac{\rho_l w_a}{(w_a - w_l)}, \quad (1)$$

where w_a and w_l are the weights of the sample in air and in the immersing liquid, respectively. Such measurements present no particular difficulties, requiring only a high precision balance and a good control and measurement of temperature, because the density of the fluid bath depends on this parameter. It is good practice to check the density of a well-known standard such as sapphire before measuring the density of several glass chips. Under these conditions, errors lower than $\pm 0.0003 \text{ g/cm}^3$ can readily be obtained for glass chips of a few tens of milligrams.

2.3 Measurements in the Glass Transition Range

In the glass transition range, it is possible to study the properties of fully relaxed supercooled liquids that do not crystallize [1, 2]. However, the high temperatures and high viscosities of the liquids then prevent Archimede-based techniques from being used. One simple approach is to measure glass density as a function of temperature and extrapolate to the fictive temperature where the density of the glass and liquid are identical. In this way, a single volume (density)–temperature coordinate of the liquid can be defined, a data point that can be

combined with measurements made at superliquidus temperatures.

A more detailed knowledge of volume in this temperature range is also possible if one simply measures temperature-dependent length changes of fully relaxed liquids in the glass transition range. However, the temperature must be low enough for the viscosity of the sample to be sufficiently high that the sample does not collapse under its own weight, nor deform under the weight of the system used to measure length change. This constraint requires viscosities higher than $\sim 10^{11}$ Pa s. Given such high viscosities, care must be taken to ensure that the time spent at a given temperature is sufficiently long for the liquid to reach a fully relaxed state. Such measurements require excellent temperature stability and can last up to several days for a single measurement, but they provide direct and precise insight into volume changes over a temperature range of typically 50 °C [1, 2]. Furthermore, such measurements strikingly highlight the difference between the instantaneous elastic response of the sample to temperature change and the longer temperature-dependent viscous response that scales with structural relaxation time (Figure 2).

An alternative method for measuring the volume of a fully relaxed liquid at low temperature uses the equivalence of enthalpy and volume relaxation in the glass transition range that has been demonstrated for silicate, aluminosilicate, and borosilicate liquids [2]. In this case, when heating a glass to the fully relaxed liquid state,

the variation of the derivative property heat capacity ($\partial H/\partial T$) as a function of temperature should show the same normalized variations as expansivity ($\partial V/\partial T$). Given that heat capacity may be readily measured at all temperatures across the glass-to-liquid transition and that expansivity may be measured to temperatures at least as high as the peak associated with hysteresis, the expansivity of the relaxed liquid just above the glass transition can be inferred [3].

2.4 Measurements at Superliquidus Conditions

Superliquidus melts are typically of low viscosity, so Archimedes' principle can be used again to measure liquid density. In this case, the melt is held in an inert crucible (typically Pt or Pt/Rh) and an inert "bob" of known mass and density (and thus volume) is introduced into the molten oxide at high temperature [4]. The difference in weight of the bob measured in air and in the molten oxide provides a measure of the mass of molten oxide displaced. Knowing the volume of the bob, the density of the melt can thus be determined from Eq. (1). The difficulty associated with this sort of experiment resides in making stable measurements at the necessary high temperatures, typically in the range of 1200–1600 °C for molten silicates. Potential edge effects between the bob and the crucible and surface tension effects at the melt–air interface require the use of two bobs of different mass in order to provide robust determinations of liquid density. For this

Figure 2 Imposed variation of temperature (upper panel) and associated effect on length of a cylinder of supercooled $\text{CaMgSi}_2\text{O}_6$ liquid (lower panel). The variation in length of the sample clearly distinguishes the instantaneous (vibrational) and delayed (configurational) contributions to volume relaxation in response to a temperature change, in addition to illustrating the temperature dependence of relaxation time (after [1]). The total length change as a function of temperature may be used to quantify expansivity, this method providing a highly precise estimate of this parameter.

reason this technique is generally referred to as the *double-bob* Archimedean method. Under optimal conditions, inaccuracies as small as 0.2–0.3% in density are possible. Other techniques such as the maximum bubble-pressure method or use of falling spheres have uncertainties that are up to 10 times larger, so data acquired in those ways are not generally considered today.

For liquids melting at temperatures high enough that Pt equipment may no longer be used, crucibles and bobs can be made of other noble metals such as Ir, extending the possible temperature range to $\sim 1800^\circ\text{C}$. Above such temperatures it becomes difficult to find materials that are rigid enough to contain the melt while remaining inert. In this case containerless levitation techniques can now be employed. For example, a laser-heated sphere of known mass can be suspended on a jet of inert gas imaged in 3-D and its volume measured as a function of temperature. However, in light of the experimental difficulties associated with temperature control and measurement on the one hand and variations in the shape of the sample on the other, the inaccuracies of such measurements are at this moment three or four times higher than for the Archimedean techniques [5].

2.5 Compressibility and the Pressure Dependence of Density

The variations of volume with pressure are typically determined in one of two complementary ways. First of all, use may be made of the fact that the velocity of wave propagation in a liquid (v) is a function of density (ρ) and the adiabatic bulk modulus (K_s) according to the equation

$$K_s = \frac{1}{\beta_s} = \rho v^2. \quad (2)$$

It should be appreciated, however, that if the characteristic timescale of the wave (i.e. the inverse of its frequency) is shorter than the structural relaxation time of the liquid, then some fraction of energy may be transported by shear waves. In this case, the bulk modulus has contributions from both longitudinal modulus and shear modulus. It is thus essential to measure the speed of wave propagation over a wide range of frequencies to ensure that a constant value is determined, indicating that the bulk modulus is that of a fully relaxed liquid. For the case of sound waves in the kHz to MHz range, this constraint typically means studying liquids whose shear viscosity is less than 10 Pa s.

Use of ultrasound techniques to measure the compressibility of liquids dates back to the nineteenth century, but such techniques were dramatically improved by the advent of interferometry in the early twentieth century and then subsequently adapted in the mid-twentieth

century to the high-temperature measurements of molten oxides [6].

More recently the Brillouin scattering technique has been used to measure the compressibility of molten silicates up to temperatures exceeding 2300 K [7]. Because this technique employs hypersonic frequencies (a few tens of GHz), structural relaxation is negligible, and only the vibrational (glassy) contribution to compressibility is measured in this case. The difference between fully relaxed compressibilities measured using ultrasonic frequencies and the fully unrelaxed value determined using hypersonic frequencies can be used to derive the configurational contribution to compressibility [7]. Despite the constraints of high temperature, adiabatic moduli may be determined with these techniques to within 1%, allowing reasonable extrapolation of density around the chosen reference pressure (most conveniently 1 bar).

On the other hand, when pressure is much greater than 1 bar, a direct measurement of density is to be preferred to provide a well-constrained equation of state, including the pressure dependence of compressibility. In this respect, the most commonly employed experimental technique consists of bracketing the density of a high-pressure liquid relative to the known densities of minerals or metals such as boron nitride, platinum, graphite/diamond, or refractory olivine. In this case, a capsule containing the liquid of interest is placed within a piston-cylinder or multi-anvil device in which pressure may reach up to ~ 25 GPa. Two spheres of the solid whose equation of state is well known are added to the capsule, one at each extremity (i.e. top and bottom). After a sufficient time spent at high temperature and pressure, one determines whether the spheres sink or float in the liquid (thus the name sink/float technique). This assessment may be made based on *ex situ* techniques, that is to say, after quenching the sample and then determining if the spheres end up at the top or the bottom of the capsule [8]. Alternatively, with the advent of synchrotron facilities, it is now possible to observe the movement of a sphere within the liquid *in situ* at high pressure and temperature. Again, sinking and floating spheres indicate whether or not markers are denser than the melt.

With these techniques, the result of a given experiment does not provide a direct measurement of the density of the liquid, but rather an open-ended bracket. Precise determination of liquid density thus ideally requires a neutral buoyancy experiment bracketed by a sink and a float at slightly lower and higher pressures. Further complications include uncertainties in the equation of state of the density markers and potential chemical reaction between the markers and the liquid of interest. For all these reasons, high-pressure densities measured in this way typically have inaccuracies of several percent, which is minor relative to the 25–50% change in density that

typically occurs over pressure ranges of ~ 10 GPa [8]. In this pressure range, more refined *in situ* X-ray techniques with synchrotron radiation have recently been used to measure density from the absorption coefficients of the liquids and the compressibility from the structure factor q (cf. Chapter 2.2) [9].

At pressures higher than those accessible to the sink/float technique, liquid densities may be measured from shock-wave compression. In this technique a projectile is launched at variable velocity against a liquid sample held in an inert metallic capsule. From determination of the shock Hugoniot, that is to say, the covariation of shock and particle velocities in the sample, the pressure–volume coordinates of the sample during isentropic compression can be derived. The extreme conditions and elevated cost of the experiment, the short timescales involved (potentially leading to incompletely relaxed states), and the necessary presence of capsule materials in front of and behind the liquid sample make such measurements challenging, but densities can be measured with an imprecision on the order of 1% for pressures up to at least 250 GPa [10].

3 Measured Density Variations

3.1 Superliquidus Densities at 1 bar: Variations as a Function of Composition

The superliquidus volumes of the common network-forming oxides such as SiO_2 , B_2O_3 , P_2O_5 , and GeO_2 have all been determined, but these are not necessarily the easiest materials to investigate owing to their high liquidus temperatures and viscosities (e.g. SiO_2), their volatility (e.g. B_2O_3), or their corrosive nature (e.g. P_2O_5). Indeed, the direct measurement of the molar volume of pure liquid SiO_2 is so challenging that indirect measurements such as extrapolation of densities to pure SiO_2 from binary systems, use of the melting curve of cristobalite, and measurements on quenched glasses are preferred measures of the molar volume and expansivity for this oxide [11].

Since the 1950s, early systematic interest in the density of molten oxides was largely driven by the field of metallurgy, with the acquisition of data in many binary and ternary systems containing silica as the principal oxide, diluted by various network-modifying oxides, such as SiO_2 – Na_2O or SiO_2 – CaO (e.g. [4]). The densities measured in these simple systems demonstrate that for mole fractions of SiO_2 ranging from 0.35 to 0.85, molar volume is approximately a linear function of composition at fixed temperature. This observation indicates that in terms of volume, silicate liquids can be considered as ideal solutions (i.e. there is no excess molar volume associated with

mixing of different components), offering the possibility to construct simple predictive models for superliquidus density (e.g. [4, 12]). If the same is true at all temperatures and pressures, then to a first approximation the bulk density of complex liquids can be reconstructed from a set of partial molar volumes at reference conditions (V_i°), partial molar expansivities (dV_i/dT) and partial molar compressibilities (dV_i/dP), one for each oxide component.

$$V_{\text{liq}}(T, P, X_i) = \sum X_i \left[V_i^\circ + \frac{dV_i}{dT}(T - 1673) + \frac{dV_i}{dP}(P - 1) \right], \quad (3)$$

where $V_{\text{liq}}(T, P, X_i)$ is the molar volume of the liquid at temperature T (in K) and pressure P (in bars), and V_i° are the partial molar volumes at reference conditions of 1673 K and 1 bar.

In subsequent years, the earth science community spearheaded the acquisition of new data across a broad compositional range in multicomponent systems containing up to 10 different oxides, albeit still concentrated on liquids dominated by silica. This wealth of new high-quality data made it possible to refine the predictive models for superliquidus density, confirming that simple temperature-dependent partial molar volumes that are constant across wide compositional ranges are generally an excellent first-order approximation, both for aluminosilicate and borosilicate melts [13, 14; Table 1).

In detail, certain authors have highlighted deviations from ideality that are typically assumed to originate in one of two ways. First of all such nonidealities may represent an excess volume resulting from the interaction of two or more oxide components. Alternatively, a given oxide component may have more than one possible structural environment in the melt, each one having a different partial molar volume.

For the first case, pushing compositions to extremes can reveal the limits of the ideal mixing approximation. This is illustrated by measurements across the CaO – Al_2O_3 – SiO_2 ternary that include data for CaO -free, Al_2O_3 -free, and SiO_2 -free liquids [20]. However, even in this extreme case, a single excess volume term between CaO and SiO_2 is sufficient to rationalize all the data.

An illustration of the second case is provided by TiO_2 , an oxide component that has a partial molar volume in silicate melts that increases with the addition of alkalis (e.g. Figure 3a). This increase can be understood by the associated increase in the mean coordination number of Ti in the liquid (Figure 3b). Similar effects can also be found for expansivities, the thermal expansion of the TiO_2 component decreasing as alkali content increases [19].

The case of B_2O_3 is also of interest in this respect as boron occurs in both threefold and fourfold coordination in silicate and alumina-silicate melts, the relative

Table 1 Partial molar volumes, thermal expansions, and compressibilities of oxide components of silicate liquids.

^a Values from [13].^b For TiO₂, the values shown are those typical of geological liquids [13]. In detail, the partial molar volume of this component is a function of coordination number, as illustrated in Figure 3.^c Values from [14], applicable for B₂O₃ < 15 wt %.^d For Fe₂O₃, the values shown here are taken from [15] and correspond to liquids rich in alkalis for which the coordination number of Fe³⁺ is close to 5.^e For FeO, the values shown here are taken from [16] and correspond to liquids poor or devoid of alkalis.^f Values from [17], for a SiO₂ partial molar volume of 26.75 cm³/mol at 1400 °C.^g Value from [18].

proportion of these structural roles being a sensitive function of alkali content (Chapter 7.6). Detailed investigation of the density of boron-containing liquids indicates that distinguishing threefold and fourfold boron can lead to a better reproduction of the experimental data and that the partial molar volume of a B₂O₃ component with only trigonal B³⁺ is close to the value measured in pure liquid B₂O₃ [14]. Because the speciation of B³⁺ is not generally known in the liquid at high temperature, however, it has been concluded that a single partial molar volume for the B₂O₃ component is sufficient for practical purposes, at least for liquids containing less than ~15 wt % B₂O₃ [14].

A third situation of note is that of multivalent cations, for which each oxidation state may be expected to be associated with a different partial molar volume. The case of iron (as FeO and Fe₂O₃) is of particular importance

given the large concentrations of this element in melts of geological and metallurgical interest. When investigating these liquids, the first difficulty is thus controlling and/or measuring the relative proportions of FeO and Fe₂O₃, which depend on temperature, oxygen fugacity, and melt composition (Chapter 5.6). Of note is the fact that the temperature dependence of redox ratio may thus lead to volume changes that are not simply the effect of expansivity.

Furthermore, both Fe²⁺ and Fe³⁺ exist in several coordination states, ranging from 4 to 6 (Chapter 2.6), complicating the interpretation of available volume data. The most recent considerations of this issue have thus endeavored to study liquids containing only one valence state of iron. Data from a wide range of simple alkali-bearing and alkali-free systems indicate that the partial molar volume

Figure 3 Effects of structural changes on the volume properties of TiO_2 -bearing potassium silicate liquids [19]. (a) Increase of the partial molar volume of the TiO_2 component with K_2O content at 1373 K. (b) Average coordination number of Ti in the quenched glasses.

of Fe_2O_3 may show significant variations, consistent with changes in average coordination state. However, the partial molar volume of Fe_2O_3 is independent of both composition and temperature in alkali-rich liquids, with a value consistent with a coordination number of Fe^{3+} of approximately five [15], which may be used for practical purposes. For FeO , measurements in a wide range of alkali-poor liquids indicate that a single temperature-dependent partial molar volume is sufficient to describe the data [16]. However, it should be appreciated that this partial molar volume is consistent with a coordination number of Fe^{2+} of almost six, leading to the possibility that for liquids in which Fe^{2+} occurs in a lower coordination state (e.g. upon addition of significant alkalis), the relevant partial molar volume could be lower.

A final case of interest is the influence of volatile species such as water or CO_2 . On the one hand, the equilibrium solubility of such species is very low at atmospheric pressure, making their influence on density minor at best at these conditions. On the other hand, at the higher pressures associated with partial melting of the Earth's

interior, these volatiles may have a significant and critical effect on liquid density. Making detailed measurements *in situ* at high temperature and pressure is particularly challenging. Alternatively, fully relaxed volatile-bearing liquids may be studied in the glass transition range at one bar using glasses quenched from high pressure. In this way the partial molar volume of H_2O has been quantified and found to be generally independent of the silicate melt composition, the total water concentration, and the speciation of water [21]. The partial molar volume of H_2O derived at 1000 °C is greater than that typical of bulk anhydrous silicates, such that the effect of 1 wt % dissolved H_2O on the density of a basaltic melt is equivalent to increasing the temperature of the melt by ~400 °C or decreasing the pressure by ~0.5 GPa.

3.2 Variations in Density over Large Temperature Ranges

In general, data from superliquidus temperatures are obtained over an interval on the order of 500 °C. In this range, a constant thermal expansivity is sufficient to describe the data, with a few rare exceptions such as molten B_2O_3 [22], the latter possibly indicating major temperature-dependent structural changes. Given that superliquidus volume generally shows ideal mixing, the same is to be expected for expansivity (that is to say, $\partial V/\partial T$, not to be confused with the thermal expansion coefficient α). This is indeed found to be the case ([6]; Table 1). For silicate melts, the strong covalent nature of the Si–O bond is such that there is little change in the Si–O length, thermal expansion being driven by expansion of the Si–O–Si angle. For this reason, the partial molar thermal expansion of SiO_2 is smaller than those of other oxides, whereas among the network-modifying oxides such as K_2O or CaO , the partial molar thermal expansion coefficients are inversely correlated with cation field strength, a trend also observed for partial molar heat capacities.

Given that relaxed liquid volumes and expansivities can also be defined just above the glass transition, combining all available data provides access to variations in volume over a temperature interval that is typically in excess of 1000 °C. If a single V – T coordinate at the fictive temperature is used, within nominal experimental error, a case might be made for expansivities that are constant over this entire temperature range. However, if all available measurements in the glass transition range are used, including multiple V – T coordinates and expansivities derived from the equivalence of volume and enthalpy relaxation, it becomes clear that expansivity typically decreases with increasing temperature (Figure 4). This decrease in expansivity appears most pronounced in depolymerized melts of low silica and alumina content,

Figure 4 Temperature-dependent nature of the thermal expansion coefficient of $\text{CaMgSi}_2\text{O}_6$ liquid [1]. Thick line at ~ 1000 K: direct volume measurements [1]. Other line in the glass transition range: values derived from the assumed equivalence of structural and enthalpy relaxation [3]. Thin dashed line: extrapolation with a constant thermal expansion coefficient of the volumes measured in the glass transition range, not matching the individual measurements made at superliquidus temperature with a double-bob Archimedes technique.

such as diopside ($\text{CaMgSi}_2\text{O}_6$) melt (Figure 4), but less prominent in more polymerized liquids [1]. These data therefore argue for caution when extrapolating predictive models outside of the range where experimental data were collected.

Below the glass transition, density continues to be a function of temperature, but then expansivity values become those typical of solids, i.e. much lower than those of fully relaxed liquids. From a theoretical point of view, calculation of room-temperature density requires knowledge of the fictive temperature, the density of the liquid at that temperature, and the expansivity of the glass. In practice, glass densities can be calculated to a reasonable approximation with the partial molar values derived from extensive databases obtained on usual samples, typically obtained by the glassmaking industry (e.g. [23]).

3.3 Variations in Density with Pressure

As indicated above, the compressibility of superliquidus melts can be measured by ultrasound techniques if the density is known. Since the 1980s liquids covering a wide enough range of composition have been studied at one bar to quantify the compressibility of individual oxide components within the framework of Eq. (1) (e.g. [6, 13]). Indeed, once elements with multiple valence states and/or coordination numbers are taken account of, it is found that a set of partial molar compressibilities (expressed as $\partial V/\partial P$, not β) is sufficient to describe the pressure dependence of complex liquids (Table 1). For silicate melts, the open structure and strongly covalent

nature of the Si–O bond are such that low-pressure compression takes place through changes in the Si–O–Si angle, leading to a partial molar compressibility for SiO_2 that is high compared with those of network-modifying oxides. Among the network modifiers, there is again a negative correlation between compressibility and cation field strength. In detail, the compressibility in ternary aluminosilicate liquids appears to have non-ideal contributions, with excess terms between Al_2O_3 and both CaO and Na_2O in the $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ and $\text{Na}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ systems, indicating complexities and differences in compression mechanisms [24].

One can highlight such complexities by combining 1-bar data, low-pressure compressibility, sink/float data, and shock-wave data for a given composition to follow the variation of volume over a wide range of pressure. Where this is possible, volume changes are typically described by empirical equations of state (EOS) inspired by those used for crystalline materials, for example, the Birch–Murnaghan equation:

$$P = \frac{3}{2}K_0 \left[\left(\frac{V_0}{V} \right)^{7/3} - \left(\frac{V_0}{V} \right)^{5/3} \right] \left\{ 1 + \frac{3}{4}(K'_0 - 4) \left[\left(\frac{V_0}{V} \right)^{2/3} - 1 \right] + \frac{3}{8} \left[K_0 K''_0 + (K'_0 - 4)(K'_0 - 3) + \frac{35}{9} \right] \left[\left(\frac{V_0}{V} \right)^{2/3} - 1 \right]^2 + \dots \right\}, \quad (4)$$

where K_0 , K'_0 , and K''_0 are the bulk modulus and its first- and second-order pressure derivatives, all for $P = 1$ bar. For molten silicates the bulk modulus increases with increasing pressure, and for a given liquid, a single equation may typically be fitted to all available volume–pressure data across the widest pressure range possible. For example, a single third-order Birch–Murnaghan isentrope centered at 1 bar and 1573 K plus a Mie–Grüneisen thermal pressure approximation reproduces the measured volumes of fayalite melt (Fe_2SiO_4) from room pressure to 161 GPa [25]. However, *in situ* quantification of the compressibility of fayalite liquid at pressures near 5 GPa is not in agreement with the value derived from the previously proposed EOS over the relevant pressure range [9].

This example illustrates that equations of state used successfully for crystalline solids may not necessarily be applicable to molten oxides over large pressure ranges. The reason for this is that, in contrast to crystalline materials, melts may experience gradual changes in the coordination number of one or more cations over certain pressure intervals. For example, in fayalite liquid, the coordination state of Fe increases from ~ 5 to ~ 7 between room pressure and 7.5 GPa, explaining the “anomalous” variation of compressibility. A similar transition, albeit

at higher pressure, has also been proposed for Mg in liquid forsterite (Mg_2SiO_4). Likewise, B, Ge, Al, and Si undergo transitions to higher coordination number over a different pressure ranges, B^{3+} and Al^{3+} at pressures lower than 5 GPa, whereas conversion of Ge and Si from fourfold through fivefold to sixfold coordination takes place at pressures of 5–10 and 20–40 GPa for pure GeO and SiO_2 respectively [9], although some interesting amorphous–amorphous transitions may also occur in these latter two systems (Chapter 3.9).

Similar transitions are also found for static compression of amorphous solids and even for crystalline materials that are observed to undergo amorphization when subjected to GPa pressures (Chapter 3.10). All of these structural changes are expected to influence bulk density. In the liquid state they should in principle be taken into account when defining and fitting a volume–pressure–temperature equation of state. On the other hand, given the unrelaxed nature of glasses, care must be taken when interpreting density variations of amorphous solids. This care involves both quantifying the fictive pressure of the glass if it is formed by cooling of a liquid at high pressure and identifying permanent vs. reversible changes in density upon compression/decompression.

4 Practical Applications

One of the most obvious practical consequences of density changes concerns the variations in volume associated with cooling through the glass transition, which is commonly used in physical tempering (Chapter 3.12). In the glassy state, volume changes are also important if the glass is in contact with a substrate, as a difference in expansivity can result in the generation of stresses at the interface during heating/cooling cycles. The same is also true for materials that contain an intimate mixture of glass and crystals, for example, glass ceramics used as kitchen hotplates. Independently of the interfaces between a glass and other materials, the thermal expansivity of amorphous oxides may be of importance in itself for certain applications, in particular those where stringent constraints on the geometry of optical path are required. The mirrors and lenses used for astronomical telescopes, including the Hubble space telescope, are a particularly good example of such an application where ultralow expansivity is required. Such glasses are typically a mixture of SiO_2 and TiO_2 , particularly refractory compositions that require innovative fabrication processes such as flame hydrolysis.

In addition to their relevance to industrial applications, the volumes of molten oxides are also of considerable importance in geological systems. Notwithstanding the question of convection alluded to in the Introduction,

the solubility and partitioning behavior of minor elements in silicate melts are directly influenced by liquid density. For example, the solubility limit of noble gases (He, Ar, etc.) in silicate melts is a function of the “ionic porosity” of the liquid, that is to say, a measure of the free volume that it not occupied by the atoms. One consequence of this fact is that dramatic decreases in solubility may occur at high pressure as the density of the liquid increases as a result of structural modifications such as changes in the coordination states of network-forming cations (e.g. [26]). Furthermore, from a thermodynamic standpoint, partial molar volumes also influence how oxide components will partition between liquid and solid phases, as illustrated for metal–silicate partitioning of the oxides GeO_2 and Ga_2O_3 [27].

Finally, as a fundamental contribution to the pressure dependence of free energy, volume has a critical influence on high-pressure phase equilibria. This is most readily illustrated by the well-known Clausius–Clapeyron relation stating that the pressure dependence of the fusion temperature of a congruently melting phase is

$$\left(\frac{dP}{dT}\right) = \left(\frac{\Delta S}{\Delta V}\right), \quad (5)$$

where ΔS and ΔV are the entropy and volume of fusion. Because the entropy of a liquid is always greater than that of a solid of the same composition, this relation implies that the sign of the slope of the liquidus is determined by the density difference between the solid and liquid. Given that the compressibility of liquids is generally greater than that of solids, volumes of fusion qualitatively decrease with increasing pressure and may even become negative (i.e. liquids are denser than crystals). In this case the Clapeyron slope may vary from positive to negative, the melting temperature being independent of pressure where crystal and liquid have the same density. In more complex multicomponent systems, the situation is not so simple, and neutral buoyancy is not necessarily related to a change in sign of the liquidus slope (e.g. [28]). On the other hand, the question of neutral buoyancy during melting of planetary mantles is a question of some significant interest given that such a “density trap” could have significant geochemical and geophysical consequences, so even today this possibility raises significant interest in the geological community [29].

5 Perspectives

Over the coming years, a better understanding the density of amorphous oxides will ultimately be driven by new experimental data that constrain the details of volume changes as a function of composition, temperature, and pressure. In this respect, direct determination of derivative

properties such as expansivity and compressibility, in particular at high pressure, will be particularly important. New and innovative techniques involving synchrotron radiation may help make significant progress (e.g. [9]), although solid–liquid partitioning behavior at high pressure remains an approach that may have more to offer (e.g. [30]). In any case, it is becoming increasingly clear that detailed interpretation of volume data cannot be made without quantification of the structure of the melt and any changes in structure that may occur upon heating and/or compression. The possibility to study liquids *in situ* at high pressures and temperatures will be of critical importance given that quenched glasses represent the structure of the liquid at a single P – T coordinate and that retrieval of the relevant fictive temperatures and pressures is not a trivial issue (e.g. [31]). Here again synchrotron-based techniques, including new approaches such as X-ray Raman scattering, may help make significant breakthroughs. Finally, the dramatic increases in computing power are revolutionizing techniques based upon numerical modeling such as molecular dynamics and *ab initio* calculations (Chapters 2.9 and 2.10). The temperature domain accessible with these techniques is now comparable to that of laboratory experiments, and the number of particles used is sufficiently large to be representative of a bulk liquids. For these reasons, such modeling efforts will undoubtedly lead to new insight concerning how volume and structure are related (e.g. [32]).

Thermodynamic Properties of Oxide Glasses and Liquids

Pascal Richet¹ and Dominique de Ligny²

¹ Institut de Physique du Globe de Paris, Paris, France

² Department of Materials Science and Engineering, Friedrich Alexander Universität Erlangen-Nürnberg, Erlangen, Germany

1 Introduction

In Molière's famous seventeenth-century play *The Middle-Class Gentleman*, the main character Mr. Jourdain is a *nouveau riche* who is delighted to learn from his Master of philosophy that he had been speaking in *prose* for 40 years without knowing it. Would ancient glassmakers have been proud to learn that they had been likewise unknowingly practicing *thermodynamics* ever since the beginnings of their craft millennia earlier? Along with their fellow ceramists and metallurgists, they did it empirically to make the best out of their limited fuel and material resources. When the new science of thermodynamics eventually emerged at the beginning of the nineteenth century, fundamental insights were at last gained to improve the energy efficiency of high-temperature processes (Chapter 10.9). Leaving aside the glass itself, interest was first paid to the combustion reactions and heat storage by refractory materials. Since then, however, glass has entered the scene with approaches that have progressively become fairly complex as exemplified in widely different fields such as energy-efficiency assessments (Chapter 9.8), fluid-dynamics simulations of the whole melting and forming processes (Chapter 1.7), and melting reactions (Chapter 1.3) to which the present chapter is most relevant.

In glassmaking, the main thermal properties required for thermodynamic calculations are the high-temperature heat capacities (C_p) and enthalpies of formation (ΔH_f°) of the melts from the raw materials. Interestingly, such measurements were pioneered in the late nineteenth century by geophysicists at the request of

William Thomson (1824–1907), better known as Lord Kelvin, within the context of the controversy over the age of the Earth ([1] and ref. therein). Since then, interest in the thermodynamic properties of glasses and melts has been strongly enhanced by the development of phase-equilibria calculations (Chapter 5.3), which are now extensively performed to predict liquidus temperatures under most varied conditions in industry as well as in geology.

These models are only as good as their input data are. In this respect, an important practical difficulty stems from the wide composition ranges to be dealt with. This constraint makes it necessary to establish additional models for predicting reliably these input data as a function of not only composition but also temperature and, in geophysics, of pressure. Such models can be purely empirical, but it is preferable to give them a physical basis and to relate them to well-defined structural features for interpolations and, still more, for extrapolations made outside the composition ranges from which they have been established. In addition, one should not overlook the fact that the glassy state raises by itself interesting thermodynamic problems, especially at low temperatures (Chapter 3.4), which are related to the fundamental problem of the glass transition (Chapter 3.3).

In the present chapter, the operational applicability of the concept of entropy (S) to glasses in relation to their non-equilibrium nature must be justified before the experimental methods used to determine thermodynamic properties from the vicinity of 0 K to superliquidus temperatures are briefly summarized. The effects of chemical composition on thermodynamic properties can then be reviewed. Including such issues as the boson peak and residual entropy, the heat capacity and entropy are examined in four distinct temperature ranges: (i) below 50 K, where medium-range order is mainly involved; (ii) up to 300 K,

Reviewers: A. Takada, Research Center, Asahi Glass Co. Ltd., Yokohama, Japan
A. Whittington, Geological Sciences, University of Missouri, Columbia, MO, USA

where the influence of short-range order prevails; (iii) between room temperature and the glass transition, where compositional effects tend to vanish; (iv) above the glass transition, where much complexity is introduced by configurational degrees of freedom. Finally, the problems raised by determinations of enthalpies of mixing and of formation are briefly addressed. Because these topics are treated elsewhere, the physics of low-temperature heat capacity anomalies (Chapter 3.4) as well as thermal conductivities and diffusivities (Chapter 4.5) are not dealt with.

2 Thermodynamic Functions

2.1 The Entropy Problem

Determining the entropy change between two thermodynamic states requires the existence of a reversible pathway between them. The fact that glasses are nonequilibrium substances may thus seem to be problematic in this respect. Below the glass transition range, however, the structure of a glass is fixed so that any irreversible relaxation can be neglected during a calorimetric measurement. It is through the glass transition that difficulties arise since heat capacities measured upon heating and cooling differ, and so do entropy variations between two temperatures calculated along these distinct pathways (cf. Chapter 10.11). But the entropy created irreversibly across the glass transition is small enough to be operationally neglected and to allow the residual entropy of the glass at 0 K to be determined from calorimetric cycles involving the crystalline, liquid, and glass forms of substance [2]. The procedure has also been followed for other nonequilibrium systems such as ice, CO, and other orientationally disordered crystals with the appropriate thermochemical cycles (e.g. [3]).

Although long accepted [4], the notion of residual entropies at 0 K for amorphous or disordered substances has recently been rejected as inconsistent with the fact that the loss of ergodicity at the actual glass transition would imply the simultaneous loss of any configurational entropy because the system would become unable to explore all its configurational states [5, 6]. Against this *kinetic* picture, simple theoretical considerations [7] and detailed analyses of calorimetric measurements [8] have supported the *conventional* view. The origin of the divergence between the two pictures is the manner in which microstates are counted in statistical-mechanical models depending on whether Gibbs or Boltzmann entropy is considered [9]. The “entropy-loss” view of the kinetic picture considers only the number of states actually visited by the system at the observational time

scale. The approach of the conventional standpoint is in contrast concerned with the probability of occurrence of the relevant states, be they actually explored or not by the system. Its important point is that energy, volume, entropy, and other extensive properties remain state variables for a system that is not in internal equilibrium. Even though more than two of these variables are needed to specify the state of the system, their values remain uniquely defined [9]. Such a picture is in particular consistent with the equivalence of the kinetics of structural, enthalpy, and volume relaxation observed for silicate melts [9], with the “additivity” of extensive variables over different macroscopic parts of a system [10] and with fundamental considerations of nonequilibrium thermodynamics [11].

2.2 Gibbs Free Energy and Stability

At constant temperature and pressure, the equilibrium state of a system is determined by the minimum of its Gibbs free energy (G). From a practical standpoint, the validity of the entropy concept for glasses has thus the important consequence to make determinations of their Gibbs free energies (G) possible, as long done for phases in internal equilibrium for which available data are assessed in thermodynamic tables and databases (e.g. [12]). If the standard pressure state of 0.1 MPa (1 bar) is denoted by $^\circ$ and the subscript f refers to formation properties from elements or oxides, these data sets include $C_p^\circ(T)$, $S^\circ(T)$, $\Delta H_f^\circ(T)$, and $\Delta G_f^\circ(T)$. The Gibbs free energy of formation of a phase from its constituting elements or oxides is

$$\Delta G_f^\circ(T_0) = \Delta H_f^\circ(T_0) - T_0 \Delta S_f^\circ(T_0), \quad (1)$$

whereas the enthalpy (H) and entropy (S) are related to the heat capacity by

$$dH = C_p dT, \quad (2)$$

$$dS = \frac{C_p}{T} dT. \quad (3)$$

The Gibbs free energy can then be calculated at every temperature with

$$\Delta G_f^\circ(T) = \Delta H_f^\circ(T_0) + \int_{T_0}^T \Delta C_{pf}^\circ dT - T \left(\Delta S_f^\circ(T_0) + \int_{T_0}^T \frac{\Delta C_{pf}^\circ}{T} dT \right), \quad (4)$$

where

$$S^\circ(T_0) = S^\circ(0) + \int_0^{T_0} \frac{C_p^\circ}{T} dT. \quad (5)$$

If a reversible phase transition takes place in the system at a temperature T_t between T_0 and T , it is taken into account via its enthalpy of transition $\Delta H_t(T_t)$, viz.

$$\Delta G_f^\circ(T) = \Delta H_f^\circ(T_0) + \int_{T_0}^{T_t} \Delta C_{pf}^\circ dT + \Delta_t H(T_t) + \int_{T_t}^T \Delta C_{pf}^\circ dT - T \left(\Delta S_f^\circ(T_0) + \int_{T_0}^{T_t} \frac{\Delta C_{pf}^\circ}{T} dT + \frac{\Delta_t H(T_t)}{T_t} + \int_{T_t}^T \frac{\Delta C_{pf}^\circ}{T} dT \right) \quad (6)$$

Application of Eq. (6) to phase-equilibria calculations may be simply illustrated at high temperatures with SiO_2 glass, liquid, and polymorphs. In plots made against temperature, the intersections of the calculated $\Delta G_f^\circ(T)$ delineate the respective stability limits of quartz, cristobalite, and SiO_2 glass and liquid. These limits are clearly seen if one takes one of these phases as a reference – say, cristobalite – and plot instead the differences between its $\Delta G_f^\circ(T)$ and those of cristobalite (Figure 1). Quartz appears to be the phase stable below 1100 K and to melt metastably at 1700 K whereas cristobalite melts itself at 2000 K. In practice, however, quartz can be kept for a while above 1100 K because the kinetics of its transformation into cristobalite, which depends on many other factors than the ΔG_f° of the transition, becomes rapid only above 1400 K [13]. Because C_p differences between the solid phases are small, however, the ΔG_f° curves have very similar slopes and their intersection temperatures usually have rather large uncertainties. If known independently from phase-equilibria experiments, such temperatures

Figure 1 Stability of SiO_2 forms as indicated by the dashed line where they have the lowest Gibbs free energies of formation (Source: Data from [13]). Slope changes in the quartz and amorphous SiO_2 curves due to the α - β and glass transitions, respectively.

in turn represent important information to ensure the internal consistency of thermodynamic data sets through appropriate adjustments of the calorimetric results to within their error margins.

2.3 Experimental Approaches

2.3.1 General Remarks

The apparent complexity of Eqs. (4) and (6) should not conceal a basic simplicity since all thermodynamic properties of a substance are determined if one knows only its heat capacity as a function of temperature along with ΔH_f° at a single temperature and the entropy at 0 K, which is by convention taken to be zero for perfect crystals. At room pressure, calorimetric experiments are thus of two kinds (Table 1) depending on whether one measures enthalpy differences between two temperatures for the same phase or between different phases at the same temperature. In the former case, one measures enthalpy differences (ΔH) for a given temperature interval $\Delta T = T - T_0$. In the latter case, one is faced with the general problem raised by the sluggishness of the reactions of interest, which makes direct heat measurements impossible. One must then devise alternate routes leading from the initial to the final state considered, along which enthalpies can be measured.

2.3.2 Heat Capacity and Enthalpy

If ΔT is large in the calorimetry experiment, then one determines C_p by differentiating analytical expressions fitted to the $H(T) - H(T_0)$ measured as a function of T [13]. A major advantage of this *drop-calorimetry* method is that heat exchange does not need to be controlled at high temperatures where radiative transfer is predominant. Only the high temperature of the sample has to be measured precisely along with the heat released upon cooling at T_0 , which can be done very accurately if T_0 is close to room temperature. With transposed drop calorimetry, the sample is in contrast dropped from room temperature in a calorimeter kept at temperatures of up to 1000 K where the enthalpy absorbed is measured; the precision is not as high as in usual drop calorimetry, but the advantage is in some cases to ensure a final reproducible state for the sample.

If the ΔT and ΔH of the calorimetry experiment are in contrast small, as is the case of the heat brought to the sample in adiabatic calorimetry [14], then one assumes that $C_p = \Delta H/\Delta T$ with appropriate *curvature* corrections to account for the actual temperature dependence of the heat capacity of the sample between T_0 and T . Inaccuracies as low as of 0.1% can be achieved with adiabatic calorimetry but heat exchange between the sample and its

Table 1 Experimental calorimetric methods.

Method and property measured	Sample size	Inaccuracies	Effective measurement	Example of companies
Drop calorimetry with ice or other kinds of calorimeters $H_T - H_{T_0}$	1–10 g	400–1900 K 0.2% On derived C_p : 0.5%	Sample dropped from high (T) to low (T_0) temperature; $H_T - H_{T_0}$ proportional to the amount of ice melting as determined from the volume decrease of the transition (constant temperature at 273 K).	Self-made
Adiabatic calorimetry C_p	1–10 g	4–15 K: 5% 15–25 K: 1% 25–50 K: 0.5% 50–350 K: 0.1%	Measurement of the increase of temperature ΔT after a known input heat Q .	Self-made
Relaxation calorimetry (isoperibol) C_p	1–500 mg	0.1–300 K: around 1 and 2%	Relaxation time to reach the final temperature after an increase of temperature can be related to the global heat capacity of the sample and sample holder after calibration.	PPMS by quantum design
Differential scanning calorimetry (isoperibol) C_p	0.1–3 g	90–1500 K: 1–3%	Sample and reference heated under the same conditions at the same rate between temperatures T_1 and T_2 . Difference between the heat fluxes measured by power compensation or with a thermopile, integrated from T_1 to T_2 and divided by $T_2 - T_1$ to derive C_p . Calibration needed from known standards. Nonequilibrium measurement.	Netzsch, PerkinElmer, Setaram, etc.
Calvet-type calorimetry (isothermal) C_p	10–500 mg	300–1000 K ΔH : 1%	Heat flow caused by the phase change integrated as measured with a calibrated thermopile made up of a 3-D network of thermocouples; sample usually dropped into the calorimeter from room temperature.	Self-made, Setaram

surroundings becomes increasingly difficult to control when temperature increases, and blackbody radiation becomes significant, so that the measurements are usually restricted to temperatures lower than 400 K. This restriction also applies to the newer but slightly less accurate physical property measurement system (PPMS) with the heat capacity option [15] whose major advantage is to require samples of a few tens of mg, which are hundred times smaller than those needed for adiabatic calorimetry.

The other technique of differential scanning calorimetry (DSC) has become extensively used because it is rapid, commercially available, requires small samples of a few tens of mg, and lends itself to dynamic measurements made at heating rates of up to a few hundreds of degrees per minute. This is a modern form of differential thermal analysis in that it relies on comparisons made with a standard, generally corundum, whose heat capacity is accurately known, which is heated under conditions as similar as possible as those of the sample. Measurements with inaccuracies of 1% can be made if the heat fluxes to both sample and standard are measured with Calvet-type calibrated thermopiles made up of hundreds of thermocouples in series. The precision is less good, but the sensitivity may be higher, when only the differences in the power delivered to the sample and standard are measured with less expensive equipment. But the main limitation of

the technique is its upper temperature limit of about 1000 K for precise enough results, which severely restricts its uses for glass-forming liquids to compositions with low T_g 's. Interesting observations can nonetheless be made with some setups working up to 1650 K, but with errors of about 3% that are inappropriate for C_p measurements.

2.3.3 Enthalpies of Transformation

To determine enthalpy differences between different phases that do not react rapidly, the trick consists in measuring the enthalpy of solution into the same solvent of all the phases of interest (e.g. a glass and a crystal of the same composition). Conditions approaching those of infinite dilution are maintained so that the enthalpy of the transformation is simply given by the sum of the enthalpies of solution weighted by the stoichiometric coefficients of the reaction. With Calvet-type calorimeters, these solution-calorimetry measurements are also performed with thermopiles. They are made either close to room temperature with hydrofluoric acid, HF, which work well for alkali- and SiO_2 -rich materials [14], or near 1000 K with molten lead borates for more refractory samples that would leave undissolved fluoride residues in HF solutions [16]. If the heat capacities of the phases considered are known, the measured enthalpies of transition can then be referred to any other temperature.

Figure 2 Enthalpies of fusion of Na_2SiO_3 and Li_2SiO_3 directly measured by drop calorimetry as discontinuities in the $C_m = (H_T - H_{273})/(T - 273)$ curves at the melting temperatures of 1362 and 1474 K, respectively (Data from [17]). Premelting effects apparent in anomalous enthalpy increases beginning 150 and 10 K below the congruent melting points of Na_2SiO_3 and Li_2SiO_3 , respectively.

The complementary nature of the two general calorimetric methods is obvious in determinations of enthalpies of fusion. Contrary to most metals and salts, which crystallize readily upon melt cooling, oxide compounds generally vitrify at least partially. Direct measurements of the enthalpy of crystallization are thus restricted to very few cases where no glass at all is present in the sample after rapid cooling in the calorimeter (Figure 2). A more complicated procedure must in general be followed. It consists in combining the enthalpy of *vitrification* of the crystal measured by solution calorimetry at a convenient temperature T_v with the relevant enthalpy or C_p data to derive the enthalpy of fusion at the higher melting temperature T_m (Figure 3). This procedure has thus been followed to determine most of the data available for about 30 oxides and silicates [18, 19]. Because it increases with the interval $T_m - T_v$ and the C_p difference between the liquid and crystal phases, the enthalpy of fusion can actually be twice as great as the enthalpy of vitrification so that the latter generally does not represent a good approximation for the former.

2.4 The Influence of Thermal History

In view of the C_p decrease observed upon cooling at the glass transition, glasses quenched at different rates have necessarily different enthalpies (Figure 3). The enthalpy difference between two glasses having fictive temperatures T_{f2} and T_{f1} is then given by

$$\begin{aligned} \Delta H_{v2} - \Delta H_{v1} &= (C_{pl}(T_g) - C_{pg}(T_g))(T_{f2} - T_{f1}) \\ &= \Delta C_p(T_g)(T_{f2} - T_{f1}), \end{aligned} \quad (7)$$

Figure 3 Heat capacity and enthalpy above room temperature of the crystal, glass, and liquid phases of a substance melting congruently at T_m . Enthalpy of fusion at T_m determined from the enthalpy of vitrification measured by solution calorimetry at T_v and the heat capacities of the amorphous and crystalline phases between T_v and T_m . Glass enthalpy and C_p decreases at the glass transition represented for slowly and rapidly cooled glasses of fictive temperatures T_{f1} and T_{f2} , respectively.

where the subscripts l and g refer to the supercooled liquid and glass, respectively (Figure 3).

Except for hyperquenched glasses (Chapter 3.8), these effects can often be neglected because very large differences in quenching rates are needed to produce variations of fictive temperatures greater than a few tens of degrees [20]. An additional simplifying feature is that the influence of the fictive temperature on the heat capacity of the glass can be neglected as long as temperatures are not lower than about 50 K [20]. There is, however, another instance where fictive-temperature effects must be considered. It is the determination of enthalpies of mixing between *melts* from solution-calorimetry measurements made on *glasses* with widely different fictive temperatures. Because enthalpies of mixing are typically 10 times smaller than enthalpies of fusion, corrections made with Eq. (7) are no longer negligible. Meaningful results are thus obtained only if the measurements are referred with this equation either to the same fictive temperature or to a common equilibrium temperature [21] as clearly illustrated by the enthalpies of mixing in the $\text{Na}_2\text{O}-\text{SiO}_2$ system for which differences in fictive temperatures between SiO_2 and the Na-bearing glasses investigated could reach 800 K [22].

3 Low-temperature Heat Capacity and Entropy

3.1 From the Vibrational Density of States to the Heat Capacity

Like that of any solids, the heat capacity of glasses is a measure of the progressive excitation of atomic vibrations when thermal energy is brought to the substance and increases its temperature. In this respect, the fundamental feature is the vibrational density of states $g(\nu)$, i.e. the distribution of the number of vibrational modes as a function of frequency (Figure 4). For each vibration mode of frequency ν , the heat capacity is given by an Einstein function

$$c_\nu(T) = \frac{x^2 e^x}{(e^x - 1)^2}, \quad (8)$$

where x stands for $h\nu/kT$, and h and k for Planck and Boltzmann constants. The heat capacity of the glass is the integral of Eq. (7) over $g(\nu)$ from 0 to the maximum vibrational frequency ν_m :

$$C_V(T) = \int_0^{\nu_m} c_\nu(T) g(\nu) d\nu. \quad (9)$$

Neglecting the very small differences existing below 300 K between the isobaric (C_p) and isochoric (C_V) heat capacities, one then calculates the vibrational entropy from

Figure 4 Relationship between the vibrational density of states, $g(\nu)$, of SiO_2 glass and the heat capacity as given by the areas below the $g(\nu)c_\nu(T)$ functions plotted at the indicated temperatures. Data from [23].

$$S_{298} - S_0 = \int_0^{298} \frac{C_p}{T} dT, \quad (10)$$

where the residual entropy S_0 cannot be omitted because it is not zero for glasses and other disordered substances.

With increasing temperatures, modes of progressively increasing frequency (and energy) contribute to the heat capacity. For SiO_2 glass, only modes of frequencies lower than 200, 400, and 600 cm^{-1} contribute significantly to C_p below about 50, 100, and 200 K, respectively (Figure 4). Of course, these regimes do not have sharp boundaries but such simple considerations are useful to discuss the composition dependence of low-temperature heat capacities and entropies for which there is now a wealth of experimental data. These low-frequency modes involve either weak bonds or the motion of a large number of atoms and, as such, can be considered as probes of medium-range order. Indeed, it is only in this temperature range that a dependence of C_p on the thermal history of the glass is detected, the heat capacity being higher for samples with higher fictive temperatures and lower density (e.g. [20]). But C_p values below 50 K are so small that they barely contribute to the room-temperature entropy as given by Eq. (10). High-frequency modes in contrast are a direct reflection of short-range order, which involves the strongest atomic interactions and dominate the room-temperature entropy.

3.2 Oxygen Coordination of Network-modifying Cations

In a first approximation, atomic vibrations in solids may be considered to be harmonic oscillations whose frequencies decrease as the mass of the atoms involved increases and increase with the strength of their bonding (cf. $\nu = 1/[2\pi(\mu/k)^{1/2}]$ of the diatomic molecule, where μ is the reduced mass and k the force constant). For disilicate glasses (Figure 5), the heat capacities thus decrease from K to Na and Li as a result of increasing cation mass and of the increase in average bond strength caused by the decrease of the ionic radius of the alkali. In addition, they are higher for glasses than for their isochemical crystals as a result of a larger volume, which affects acoustic modes through a decrease of the bulk modulus, and of a bond-strength disordering in the network at constant volume [25]. A third factor is the presence at low frequency of the excess of vibrational modes to be described below in Section 3.5.

Nevertheless, the overall similarity of the data for glasses and crystals excludes markedly different short-range order not only in disilicate glasses and crystals but also, more generally, in binary $\text{SiO}_2\text{-M}_2\text{O}$ systems for which vibrational entropies vary linearly up to the metasilicate compositions (Figure 6). Hence, especially for potassium silicates, the average oxygen coordination

Figure 5 Low-temperature heat capacities of alkali disilicate $M_2Si_2O_5$ glasses (solid curves) and crystals (dashed curves). Data from [24].

Figure 6 Vibrational entropy of alkali silicate glasses (solid symbols) and crystals (open symbols). Source: Data from [33] and de Ligny (unpublished results).

number should be close to the value of about 5 that holds in crystals.

3.3 Oxygen Coordination of Network-Forming Cations

That the effects of oxygen coordination, or atomic packing, are much more important than those of volume (at constant coordination) is clearly illustrated by the

Figure 7 Vibrational entropy of SiO_2 and GeO_2 glasses and polymorphs against the molar volume of the phases. SiO_2 : Gl (glass), Qu (quartz), Cr (cristobalite), Tr (tridymite), St (stishovite), and Co (coesite). GeO_2 : Gl (glass), t- (tetragonal form), and h- (hexagonal form). Data for SnO_2 (cassiterite) and TiO_2 (rutile) added to complement the trend for tetragonal crystals. Data from [26, 27].

network-forming cations Si^{4+} and Ge^{4+} . For the isostructural forms of SiO_2 and GeO_2 (Figure 7), the vibrational entropy is much higher for tetrahedral than for octahedral coordination. Because Si—O and Ge—O bond distances are shorter for the former coordination than for the latter, the internal vibrational modes have lower frequencies in SiO_4 and GeO_4 tetrahedra than in SiO_6 and GeO_6 octahedra, but the ensuing lower contributions to the heat capacities are more than compensated by the effects of the C_p decreases of the lattice modes that are due to the shorter Si—Si and Ge—Ge distances between second-nearest neighbors in the dense, high-pressure phases.

A similar effect of the change of four- to sixfold coordination of aluminum is apparent in the $S_{298} - S_0$ data of sodium and calcium aluminosilicates (Figure 8). In both series, the vibrational entropies vary linearly from pure SiO_2 to the meta-aluminous compositions for glasses and low-pressure crystals, in accordance with the tetrahedral coordination reported for both Si^{4+} and Al^{3+} [19]. In contrast, the high-pressure phases of crystalline jadeite (Jd, $NaAlSi_2O_6$) and Ca-Tschermak pyroxene (CaTs, $CaAl_2SiO_6$) have entropies departing negatively from these trends because all or some of their Al is sixfold coordinated.

Figure 8 Vibrational entropy of crystals (open squares) and glasses (solid circles) along the joins $\text{SiO}_2\text{--NaAlO}_2$ and $\text{SiO}_2\text{--Ca}_{0.5}\text{AlO}_2$. 3.4 Partial Molar Entropy of Oxides in Silicate Glasses

The determining influence of short-range order on vibrational properties is also demonstrated by the fact that the entropy of silicate crystals may be calculated as a sum of entropy coefficients pertaining to oxide components characterized by the coordination number of the cation [28]. In view of the continuous nature of glass solutions, the same procedure can be applied to derive partial molar heat capacities and vibrational entropies for oxides in glasses (Table 2). The generally additive nature of $S_{298} - S_0$ (Figures 6 and 8) is confirmed by the fact that data available for about 50 different compositions can be reproduced to better than 1% with a set of composition-independent partial molar entropies.

As expected, the influence of Al speciation in aluminosilicates is clear since partial molar heat capacities (Figure 9) and entropies decrease from four- to five- and then sixfold coordination [30]. Another noteworthy feature is that two different Na_2O and K_2O components must be distinguished depending on whether the alkali element is “free” or is associated as a charge compensator with tetrahedral Al [26]. The higher entropies calculated in the latter cases indicate that association with Al causes the coordination number of the alkali to increase from the aforementioned number of about 5 to a much higher value similar to those determined for tectosilicates. But a single entropy is derived for Ca and for Mg when transforming from network modifier to a charge compensator, indicating that in contrast the environment of alkali earth

cations does not change much upon a less strong association with two tetrahedral Al^{3+} ions. As for boron, one must not only assign widely different values to three- and fourfold coordination but distinguish in the former between borons that belong to the so-called boroxol rings (Chapter 7.6) and the others (Table 2).

3.5 Calorimetric Boson Peak

For some glasses [23], additivity of the heat capacity can break down below about 50 K where there exist strong positive deviations with respect to the Debye T^3 laws commonly observed near 0 K by crystals. This calorimetric anomaly originates in an excess of modes found between 30 and 150 cm^{-1} in the vibrational density of states, known as the boson peak (Chapter 3.4), with respect to Debye model that considers a solid as an

Figure 9 Influence of the coordination state of aluminum on the partial molar heat capacities of Al_2O_3 in aluminosilicate glasses, compared with those of CaO and SiO_2 . [30].

isotropic continuum in which longitudinal and transversal acoustic waves propagate with constant velocities. Owing to this common reference to Debye model, the calorimetric anomaly will also be referred to as a boson peak. It is in fact not peculiar to glasses and other disordered solids (Chapter 3.4). As indicated by peaks in plots of C_p/T^3 against T , the calorimetric anomaly is even greater for cristobalite than for SiO_2 glass although it markedly decreases to quartz and coesite and vanishes for stishovite, which does follow Debye law (Figure 10). For SiO_2 glass, the boson peak is assigned to coupled librations of the corner-shared SiO_4 tetrahedra (at 0.3–4 THz frequencies) coexisting with sound waves [32]. Its marked decrease can also be assigned first to an increasingly compact arrangement of SiO_4 tetrahedra, which hinders librational motion, and then to the change from four- to sixfold Si coordination, which makes it impossible [19].

In binary alkali silicate glasses, the calorimetric boson peak increases in intensity and decreases in temperature from Li to Na and K (Figure 11) as replacement of large and heavy K^+ ions by smaller, more tightly bonded Li^+ ions shifts vibrational modes to lower frequencies. Additional insights can be gained in this respect from the inversions of Eq. (8) made to derive the low-frequency

Figure 10 Calorimetric boson peak of SiO_2 glass and polymorphs. Data sources in [19, 27]. Inset: maximum of the boson peak against the molar volume of the polymorphs (open square: SiO_2 glass).

part of the vibrational density of states from C_p data. Well-defined first peaks representing the excess modes are obtained in this way [33]. As expected from the linear trends of the input C_p data, their positions and intensities

Figure 12 First peak of the vibrational density of states of alkali silicate glasses as determined by inversion of low-temperature heat capacities [33]. (a) Position of the peak. (b) Intensity.

also vary linearly with M_2O content in alkali silicates (Figure 12) and point to a combination of librational modes from the SiO_2 component and localized vibrational modes for network-modifying cations [33, 34]. The intensity decrease caused by network depolymerization, which restricts librational motion, is more than compensated by increasing the intensity of localized vibrations. Despite the wide variations found in the position and magnitude of the boson peak, another strikingly simple feature is the collapse of all data on a single master curve when the temperature and maximum of the peaks are used as normalizing parameters for plotting the experimental data (Figure 13). But this universal representation remains to be accounted theoretically.

Figure 13 Universal representation of the calorimetric boson peak with the reduced variables $T/T_{\max}$ and $C_p/C_{p\max}$. Data for 20 silicate, aluminosilicate, and oxynitride glasses from [33, 34] and ref. therein.

4 High-temperature Properties

4.1 Glasses

Above room temperature (Figure 14), an important feature is that the glass transition takes place when the heat capacity becomes close to the Dulong and Petit harmonic limit of $3R/g$ atom where R is the gas constant [35]. It follows that any composition dependence tends to vanish at the glass transition where only the number of atoms in the formula unit eventually matters. Hence, the C_p

additivity observed below 300 K also obtains at higher temperatures with the simplifying feature that the specification of Al and alkalis no longer needs to be considered. This feature is illustrated by the convergence of the partial molar heat capacities of the Al₂O₃ species already under way below 300 K (Figure 9), but does not hold for boron for which there remains a large C_p difference between ^{III}B₂O₃ and ^{IV}B₂O₃.

To within their error margins, available heat-capacity and relative-enthalpy data can thus be reproduced from room temperature up to the glass transition with composition-independent partial molar heat capacities of the form (Table 3),

$$C_p = \sum x_i \left(a_i + b_i T + c_i/T^2 + d_i/T^{1/2} \right), \quad (11)$$

where x_i is the mol fraction of oxide i and the coefficients for SiO₂ and B₂O₃ are simply those of the C_p expression of the pure oxide glass [36]. If additional oxides need to be considered at not too high contents, then use can be made of the heat capacities of their crystalline forms in view of the generally small differences observed between glasses and crystals.

4.2 Liquids

As long as crystallization does not take place, there is not any change in the physical properties of melts when the liquidus is crossed. This feature applies in particular to the heat capacity, which varies smoothly from the supercooled to the stable liquid domain. In practice, experimental difficulties generally stem from incipient crystallization above the glass transition and very high liquidus temperatures. In other words, only short temperature intervals can very often be investigated in either

Figure 15 Mean heat capacity, $C_m = (H_T - H_{273})/(T - 273)$, of some aluminosilicate glasses and melts on both sides of the glass transition: An (CaAl₂Si₂O₈), Py (Mg₃Al₂Si₃O₁₂), Wo (CaSiO₃), and Di (CaMgSi₂O₆). Liquidus and glass transition temperatures indicated by arrows; data referred to 1 mol of oxide components; for clarity reasons, data for Py and Wo displaced upward by 3 and 5 J/gfw K, respectively. Data from [21].

domain. Not to introduce any bias, the most reliable measurements must rely on a single technique working from T_g to superliquidus temperatures. Even though quite a few valuable DSC measurements are now available, they are limited to restricted temperature intervals for low- T_g compositions for which high-temperature extrapolations are not warranted.

In the following, only drop-calorimetry results obtained up to 1850 K will thus be mentioned (Figure 15). If precise measurements are made both near T_g and at superliquidus temperatures, the *crystallization curtain* is not a great impediment, thanks to the reliable interpolations that can be made and make it, for instance, possible to ascertain whether or not the heat capacity of the liquid varies with temperature. In addition, the results yield the C_p changes at the glass transition (ΔC_p), which vary from about 10 to 50% and display extremely strong dependences on composition (Figure 14). This variety is exemplified by (i) window glass and sodium silicate melts whose heat capacities are constant over the whole temperature intervals investigated, which can reach 1000 K; (ii) titanosilicate melts, which show record high ΔC_p 's reaching 50%, followed by markedly negative values of dC_p/dT ; (iii) aluminosilicate melts, with ΔC_p values ranging from 10 to 30% and positive dC_p/dT values increasing in the order Mg, Ca, and Na in ternary systems [19]; (iv) other complexities found in borosilicates for which dC_p/dT is also variable without being correlated with B₂O₃ content [38].

It is beyond the scope of this chapter to discuss such differences. But it is worth noticing that some are reminiscent of those observed at low temperatures, which

are assigned to the dual structural role of cations that are either network modifiers or charge compensators for tetrahedrally coordinated cations. Likewise, it is tempting to assign the unusual heat capacities of titanosilicate melts to a decreasing extent of (Ti, Si) mixing on tetrahedral sites with decreasing temperatures, which would result in the coexistence of silicate and titanate species without unmixing at the lower temperatures [19].

From a practical standpoint, the occurrence of the glass transition when the Dulong-and-Petit limit is approached makes it possible to approximate the configurational heat capacity by the simple relation [18]

$$C_p^{\text{conf}}(T) = C_{\text{pl}}(T) - C_{\text{pg}}(T_g) = C_{\text{pl}}(T) - 3nR, \quad (12)$$

where n is the number of atoms in the unit formula, which provides values as accurate as those one would determine experimentally. Although C_p additivity is clearly observed in simple systems such as Li₂O– and Na₂O–SiO₂ or MgO–Al₂O₃–SiO₂, it breaks down in Ca and Na

aluminosilicates [19]. A model with “average” partial molar heat capacities is nonetheless useful especially for chemically complex compositions for which errors usually made with simple models compensate to a large extent (Table 4).

4.3 Residual Entropies

The residual entropy of a glass, S_0 , represents the entropy frozen in at the glass transition. It increases with increasing cooling rates. It can be determined by calorimetric methods from the entropy of melting of the crystal and the appropriate integrations of heat capacities measured between 0 K and T_m for the crystal, liquid, and glass phases (Figure 16), namely

$$S_g^{\circ}(0) = S_c^{\circ}(0) + \int_0^{T_m} \frac{C_{pc}^{\circ}}{T} dT + \frac{\Delta H_m^{\circ}}{T_m} + \int_{T_m}^{T_g} \frac{C_{pl}^{\circ}}{T} dT + \int_{T_g}^0 \frac{C_{pg}^{\circ}}{T} dT. \quad (13)$$

When melting temperatures are not too high (i.e. 1900 K at most), these measurements are possible if there exists an isochemical crystal that (i) melts congruently, so as to have $\Delta S_m = \Delta H_m/T_m$ and (ii) can be considered perfect at 0 K, so as to have a zero entropy at 0 K. These practical and thermodynamic constraints are the reason

why available data are rather scarce (Table 5). Of particular interest is the result obtained for NaAlSiO₄ whose residual entropy is smaller than that of SiO₂, on a g atom basis (i.e. per atom). Both glasses are made up of a continuous, open network of TO₄ tetrahedra whose purely topological entropies should not be widely different. The lower entropy of NaAlSiO₄ was, therefore, indicating a highly ordered Al–Si distribution, which has later been confirmed by NMR measurements [19]. That residual entropies determined from calorimetric experiments are thus making physical sense is also confirmed, among other examples, by the very low value calculated for Mg₂SiO₄ whose extremely poor vitrifiability may be assigned to the very rapid rate at which configurational entropy is lost [40].

More generally, the validity of the concept of residual entropy for glasses is also illustrated by a different approach based on Adam–Gibbs theory of relaxation processes. From the postulated proportionality between relaxation times and configurational entropy, S^{conf} , one finds that the viscosity is given by [41]

$$\log \eta = A_e + B_e / TS^{\text{conf}}, \quad (14)$$

where A_e is a pre-exponential term and B_e a parameter proportional to the Gibbs-free energy barriers opposing viscous flow. Because the temperature dependence of S^{conf} can be calculated with Eq. (11) and

$$S^{\text{conf}}(T) = S^{\text{conf}}(T_g) + \int_{T_g}^T \frac{C_p^{\text{conf}}}{T} dT, \quad (15)$$

these expressions represent a three-parameter equation for viscosity. From fits made with Eqs. (13) and (14) to data spanning wide intervals from the glass transition range to superliquidus temperatures, one then derives the A_e and B_e parameters and the residual entropy at the relevant glass transition temperature. The strikingly good agreement of these values with the values determined by calorimetric experiments thus validates the whole approach (Figure 17), which is especially useful as there is no other experimental method available for determining configurational entropies.

For hyperquenched glasses, however, very high fictive temperatures can affect entropy significantly. Provided that the fictive temperatures and relevant heat capacities are known, the entropy difference between glasses with different thermal histories is readily accounted with

$$S_g^{\circ}(0)_2 - S_g^{\circ}(0)_1 = \int_{T_{f1}}^{T_{f2}} \frac{C_{p1}^{\circ} - C_{pg}^{\circ}}{T} dT \approx (C_{p1}^{\circ} - C_{pg}^{\circ}) \ln \left(\frac{T_{f2}}{T_{f1}} \right). \quad (16)$$

As recently discussed [42], this effect could be the reason why glass fibers dissolve much more rapidly than bulk glass pieces in aqueous solutions.

Figure 17 Comparison between residual entropies derived from calorimetric and viscosity measurements. Data sources in [19].

5 Reaction Thermodynamics

5.1 Enthalpies of Mixing

In a solution, the Gibbs free energy is the weighted sum of the chemical potentials μ_i of the components

$$G = \sum x_i \mu_i = \sum x_i \mu_i^\circ + \Delta H_{\text{mix}} - T \Delta S_{\text{mix}}, \quad (17)$$

where x_i is the mole fraction of component i and ΔH_{mix} and ΔS_{mix} are the enthalpies and entropies of mixing, respectively. As already alluded to, ΔH_{mix} can be determined by solution calorimetry from the measurements made on the end-members and other compositions of the system of interest. Even when if one considers only binary or pseudo-binary joins, the number of relevant glass-forming systems is so large that the data available for some tens of joins [18] represent but a small fraction of those that would be worth investigating. Hence, the important Al–Si substitution for a number of alkali and alkaline earth cations will serve here to illustrate a few salient points [43].

These results are plotted as negatives of enthalpies of solution to reflect directly the enthalpy scale (Figure 18). Enthalpies of mixing between SiO_2 and $\text{M}_{x/2}\text{AlO}_2$ SiO_2 are negative in all systems, which attest to strong affinity between these components. The enthalpy minimum lies near 50 mol % with a depth that increases with the field strength of the M-cation from +10 to below -20 kJ/mol from Mg- to K-aluminosilicates and the relative extent of freezing-point depressions at eutectic points. Although they are directly relevant to phase equilibria, these data require the aforementioned fictive-temperature corrections for use in Eq. (17). For samples whose glass transition temperatures are higher

Figure 18 Enthalpies of solution of aluminosilicate glasses along binary joins. Data from [43].

than 700°C , the temperature of solution calorimetry, the adjustments can amount to 5 kJ/mol or more [21] to determine accurately enthalpies of mixing between SiO_2 and the most SiO_2 -poor composition investigated for a given system.

5.2 Gibbs Free Energies of Formation

As a rule, mixing of individual oxides in glass-forming systems is highly nonideal in terms of both enthalpy and entropy factors (Chapter 5.3). Because atomic interactions are essentially of a binary nature (Chapter 2.8), however, mixing of two binary systems is much less non-ideal, and so on when the chemical complexity keeps increasing. In thermodynamic modeling, it is thus advantageous to select as components not the relevant oxides but more complex entities in which the main interactions are already embodied [44]. In a given system, a natural choice then is to select for a particular composition the phases constituting the stable crystalline assemblage indicated by the phase diagram, between which the mixing enthalpies and entropies are negligibly small compared with those of the constituting oxides. In this way, a given property Y of a glass or its melt is simply approximated by the sum

$$Y = \sum x_i \cdot Y_i, \quad (18)$$

where x_i is the mol fraction of constitutional phase i and Y_i is its partial molar property, which is assumed to be independent of composition.

Taking the enthalpy of a glass at room temperature as an example, one obtains the H_i values from the available enthalpies of formation of ΔH_{fi}° of the i th crystalline phase and its enthalpy of vitrification ΔH_{vi} , i.e. $H_i = \Delta H_{fi}^\circ + \Delta H_{vi}$. If ΔH_{vi} data are lacking, then the approximation $\Delta H_{vi} \approx \Delta H_{mi}/2$ may be used. For entropies, the other rule of thumb $\Delta S_v \approx \Delta S_{mi}/3$ applies. If a glass melt above liquidus temperature is considered, the procedure is the same except that the H_i values refer to the liquid state.

To select the right set of components, use is made of the fact that in most systems of natural or industrial interest four oxides make up at least 85% of the composition and that stoichiometric compounds rarely bear more than three different oxides. Thus, the major four oxides are allotted according to existing phase diagrams while the rest is determined by normative geochemical calculations. On this basis, the composition of a complex system can be expressed unambiguously [45]. The major advantage of the method thus is that no structural information at all is needed as long as multicomponent systems (ternary and beyond in terms of oxides) are dealt with. Its usefulness is apparent in Table 6 where excellent agreement is found between the experimental and model

Table 6 Determination of the Gibbs free energies of formation from the oxides for a few glasses from calorimetric and viscosity measurements. Data in wt % and kJ/mol^a.

values of the Gibbs free energies of formation of four glasses.

6 Perspectives

That physical properties can represent a valuable source of structural information is often overlooked. Structures are determined by thermodynamics, and not the other way around. Despite any structural complexities of the amorphous state, an important simplifying feature is that properties of glasses generally vary smoothly with composition, without all the irregularities displayed by those of crystals caused by the constraints imposed by the specificities of discrete crystal structures. In other words, structural conclusions drawn from a few amorphous compositions can in general be extended readily to a much wider composition range than can be done for crystalline materials.

The conclusions are the most straightforward for solids when properties are vibrational in origin. Difficulties are much greater for liquids whose variety of mechanisms involved in temperature-induced structural changes remain elusive in spite of the enormous amount of

structural information that is being gathered with a variety of techniques [19]. The contrast with the scarcity of thermodynamic data at temperatures much higher than 1000 K is striking. Additional measurements are thus needed but the lack of commercially available high-precision equipment is a real impediment that could last and affect progress to be made either for tailoring new materials or for understanding igneous processes at all relevant scales.

A really fundamental goal will be to integrate into a consistent framework the structural and thermodynamic aspects in a way consistent with the fact that decreasing energy scales correlate with increasing interaction length scales. Recent work on melting mechanisms illustrates this kind of approach [46]. The starting point is the correlation observed between the calorimetric premelting effects displayed by Na₂SiO₃ and Li₂SiO₃ (Figure 2) and changes in the Raman spectra pointing, without significant enthalpy effects, to the production of mobile Na⁺ ions and Si—O[−] moieties that remain part of the crystalline silicate chains as negatively charged Q² species; these species then react with “normal” Q² units to cross-link the chains with Q³ species, liberating along the way “free” oxygen O^{2−} ions. Actual melting finally takes place with a sharp enthalpy change through depolymerization of silicate chains by free O^{2−} ions to form Q¹ species also observed spectroscopically, whereas the same reactions proceed in the reverse order upon crystallization.

Another field where much remains to be done is high-pressure experiments or, at least, measurements on permanently densified glasses, which are of fundamental interest in geophysics and are also catching the physicists' attention. The few available data for the pressure dependence of the enthalpy (Table 7) indeed suggest that strong composition-structure effects are also to be revealed. For completeness, one must also recall that thermodynamic and volume (Chapter 3.5) properties are closely related through the pressure derivative of the Gibbs free energy, $(\partial G/\partial P)_T = V$. Any progress made on the equations of state of melts will thus be of immediate relevance to high-pressure thermodynamic properties.

Table 7 Variations of the enthalpy (kJ/mol) of oxide glasses with the density (g/cm³).

Glass	$(\partial H/\partial \rho)_T$

3.7

Structural and Stress Relaxation in Glass-Forming Liquids

Ulrich Fotheringham

Research and Technology Development, Schott AG, Mainz, Germany

1 Introduction

An essential feature of the glassy state is the existence of configurational degrees of freedom. Both the number and the occupational state of these configurational degrees of freedom have an enormous impact on macroscopic properties such as the refractive index or the specific enthalpy and volume. Most of the configurational degrees of freedom may be considered as frozen-in below the glass transition range on any realistic timescale. If reheated into this temperature range, however, glass will undergo *structural relaxation*, i.e. the occupational state of these degrees of freedom will change which is equivalent to changes of the atomic structure. These changes will tend to minimize Gibbs free energy at the environmental temperature and they will have the impact on macroscopic properties mentioned above.

A good example of structural relaxation is the thermal shrinkage observed when glass is reheated to temperatures just below the glass transition. Said change of the specific volume is of particular importance for, e.g. high-temperature coating processes. Similarly, structural relaxation leads to what is called *refractive index drop* in precision molding of lens elements. A straightforward way to observe the glass transition range is by differential scanning calorimetry – calorimetric glass transition, see Section 3.5). In addition, glass will use this reconfiguration capability to undergo stress relaxation, i.e. time-dependent yielding to an imposed stress by viscous flow.

In this chapter, the above examples will be presented in detail to illustrate the practical relevance of structural relaxation. Then, the concept of fictive temperatures will

be introduced. At constant temperature and pressure, the time-dependence of the physical properties of a relaxing material indicates that other variables have to be defined to describe its state. This is done with fictive temperatures, which are the basis of the various models that account for the kinetics of structural relaxation. Stress relaxation is the other topic. In the transition range, the mechanical high-temperature response of glass – like a viscous liquid – and the mechanical low-temperature response – like an elastic solid – coexist. Their combined effect is called viscoelasticity: when glass is exposed to strain, stress will occur as an initial response, and this stress will subsequently decrease over time due to the above reconfiguration mechanism. There are two fundamental viscoelastic cases, the constant volume one (shear) and the constant shape one (pressure), which will both be discussed at the end of the chapter.

2 Structural Relaxation: A Few Examples

As it has already been said, the classical example of structural relaxation is the linear dependence of the refractive index on the logarithm of the cooling rate [1]. The slope is proportional to the number of configurational degrees of freedom, the occupational state of which is determined by the cooling rate. This issue will be discussed in more detail.

A second example is prestressing or toughening of glass plates (Figure 1), which hinges on viscous flow upon processing but is also influenced by the differing occupational states of the configurational degrees of freedom at the glass surface and in the glass core [2–4].

When heated above the glass transition range and then rapidly cooled, a glass plate develops a temperature gradient such that the temperature is highest in its core and

Reviewers: Paul Joseph, Department of Mechanical Engineering, Clemson University, Clemson, SC, USA
Markus Kuhr, Research and Technology Development, Schott AG, Mainz, Germany

Figure 1 Prestressing/toughening of a glass plate.

lowest at its surface. As a consequence, the surface contracts relative to the core, which results in compressive stress in the core and tensile stress at and near the surface. At temperatures above the glass transition range, these stresses relax by viscous flow. Therefore, the glass plate passes this range stress-free during further cooling, but with a (high) internal temperature gradient that gradually diminishes and finally disappears at room temperature. As a consequence, the core contracts relative to the surface, which results in tensile stress in the core and desirable compressive stress at the surface. These stresses are permanent and increase fracture toughness – as long as the glass plate is not reheated to the glass transition range.

Most of the contraction of the surface relative to the core and, then, of the core relative to the surface is due to thermal expansion. There is, however, a secondary effect due to said differing occupational states of the configurational degrees of freedom at the surface and in the core. As already stated, the occupational state of the latter depends on the cooling rate. The higher the cooling rate, the more high-energy states are occupied and vice versa. As the high-energy states are more space consuming than the low-energy ones, said secondary effect due to thermal expansion results. Owing to the comparatively low thermal conduction in glass, the cooling rate is much faster at the surface than in the core during prestressing. This results in an inhomogeneous distribution of occupational states over the plate cross-section, and in return in an additional contribution to the final contraction of the core relative to the surface.

The third example is the peak of the absorption curve of silicate glasses [5] in the Gigahertz/Terahertz range, which is a typical feature of all glass-forming systems, the so-called Boson peak. Its intensity is sensitive on the cooling rate and, thus, on the occupational state of the configurational degrees of freedom [6]. Hence, it is the relaxational state that eventually determines the course of the absorption curve in this frequency regime.

3 Structural Relaxation

3.1 Description of the Configurational State by at Least One Fictive Temperature

Usually one or more order parameters or one or more fictive temperatures (Sections 3.2–3.4) are selected to quantitatively describe the configurational state of a glass and, thus, the response of the macroscopic properties to its changes [7, 8a]. The basic idea is to take temperature as what it is in terms of thermodynamics, i.e. a distribution parameter indicating the average excitation level of every degree of freedom belonging to the thermal reservoir considered. If one makes a *Gedankenexperiment* (thought experiment) distinguishing between two thermal reservoirs consisting of degrees of freedom that are either all vibrational or all configurational (Figure 2), then one must also distinguish between two temperatures [9–11]. The first is the common temperature; the second is the distribution parameter describing the average excitation level of the configurational degrees of freedom, which is called fictive temperature.

If enough thermal energy is exchanged with the environment at a high enough rate, the vibrational and environmental temperatures are equal. If, in addition, there is also sufficient energy exchange between the vibrational and configurational degrees of freedom, complete thermal equilibrium is achieved and the temperature is uniform.

Regarding kinetics, the equilibration of vibrational and configurational degrees of freedom is a thermally activated process. What is called *glass transition range* is the temperature interval where, upon cooling, thermal activation is no longer large enough for ensuring equilibration and instead becomes too small for making equilibration possible on any realistic timescale. For the fictive temperature, this means that it remains equal to the environmental temperature above the glass transition but is frozen in at a constant value below it. This value is

Figure 2 Imaginary separation of glass into two thermal reservoirs containing either the vibrational degrees of freedom (occupation number $\propto \exp(-i \cdot h\nu/kT)/Z$, $i = 1, \dots, \infty$, ν vibrational frequency, h Planck's constant, $Z = \sum \exp(-i \cdot h\nu/kT)$ partition function for one vibrational degree of freedom) or the configurational degrees of freedom (for the two state examples shown here: occupation number ground level $\propto 1/Z'$, occupation number upper level $\propto \exp(-\Delta/kT)/Z'$, $Z' = 1 + \exp(-\Delta/kT)$ partition function).

determined by the actual equilibration kinetics and the applied cooling rate.

A shortcoming affects the description of the configurational state of a glass with a single fictive temperature, however, because this picture implicitly assumes strong coupling, i.e. an intense exchange of energy, between all configurational degrees of freedom to ensure that their average excitation levels follow a single distribution parameter. Coupling between configurational degrees of freedom is only indirect, however, because there is no direct energy transfer path between them. Rather, this energy transfer involves the vibrational degrees of freedom as mediator and runs this way: one configurational degree of freedom – vibrational degrees of freedom – other configurational degree of freedom. Thus, the coupling between the configurational degrees of freedom depends on the excitation level of the vibrational degrees of freedom so that it is subject to thermal activation itself.

Therefore, a set of fictive temperatures is required for the description of the configurational state of a glass. In other words, the thermal reservoir containing the configurational degrees of freedom must be split into a number of sub-reservoirs, each having a fictive sub-temperature as a distribution parameter. From a theoretical standpoint, this change makes the concept less satisfactory than expected, but it has the major advantage of leading to very useful quantitative predictions of certain glass properties.

3.2 Prediction of Glass Properties from Temperature and Fictive Temperature(s)

Such quantitative models first rely on the assumption that vibrational state and configurational states may be separated, i.e. that changes in macroscopic properties such as the enthalpy H or the volume V of a glass sample of mass M may be split into a vibrational and a configurational part and thus be written:

$$\begin{aligned} dH &= dH^{\text{vib}} + dH^{\text{conf}} \\ dV &= dV^{\text{vib}} + dV^{\text{conf}} \\ &\dots \end{aligned} \quad (1)$$

The second assumption is that any macroscopic property responds linearly to infinitesimal changes in both the environmental and the fictive temperatures:

$$\begin{aligned} dH/M &= c_p^{\text{vib}} \cdot dT + c_p^{\text{conf}} \cdot dT_f \\ dV/V &= 3\alpha^{\text{vib}} \cdot dT + 3\alpha^{\text{conf}} \cdot dT_f \end{aligned} \quad (2)$$

(one fictive temperature)

...

or

$$\begin{aligned} dH/M &= c_p^{\text{vib}} \cdot dT + c_{p,1}^{\text{conf}} \cdot dT_{f,1} + \dots + c_{p,n}^{\text{conf}} \cdot dT_{f,n} \\ dV/V &= 3\alpha^{\text{vib}} \cdot dT + 3\alpha_1^{\text{conf}} \cdot dT_{f,1} + \dots + 3\alpha_n^{\text{conf}} \cdot dT_{f,n} \end{aligned} \quad (3)$$

(n fictive sub-temperatures)

...

where c_p is the specific heat at constant pressure and α the linear coefficient of thermal expansion (3α = volume coefficient of thermal expansion) [8a].

For convenience, one writes in the case of n fictive sub-temperatures:

$$\begin{aligned} dH/M &= c_p^{\text{vib}} \cdot dT + c_p^{\text{conf}} \cdot (v_1 \cdot dT_{f,1} + \dots + v_n \cdot dT_{f,n}), \\ v_i &= \frac{c_{p,i}^{\text{conf}}}{c_p^{\text{conf}}}, \quad c_p^{\text{conf}} = \sum_{i=1}^n c_{p,i}^{\text{conf}} \\ dV/V &= 3\alpha^{\text{vib}} \cdot dT + 3\alpha^{\text{conf}} \cdot (v_1 \cdot dT_{f,1} + \dots + v_n \cdot dT_{f,n}), \\ v_i &= \frac{\alpha_i^{\text{conf}}}{\alpha^{\text{conf}}}, \quad \alpha^{\text{conf}} = \sum_{i=1}^n \alpha_i^{\text{conf}} \\ &\dots \end{aligned} \quad (4)$$

and may also define a weighted mean value of the fictive sub-temperatures by

$$T_f := \sum_{i=1}^n v_i \cdot T_{f,i}. \quad (5)$$

where the v_i coefficients are assumed to be the same. In this manner, one obtains [8a]:

$$\begin{aligned} dH/M &= c_p^{\text{vib}} \cdot dT + c_p^{\text{conf}} \cdot dT_f \\ dV/V &= 3\alpha^{\text{vib}} \cdot dT + 3\alpha^{\text{conf}} \cdot dT_f \end{aligned} \quad (6)$$

Note that a change dT_f of this weighted mean (and any resulting change dH , dV , or anything else) may be caused by different sets of $dT_{f,i}$ leading to the same $dT_f = \sum v_i dT_{f,i}$. Together with a kinetic model for the fictive temperature(s), Eqs. (2), (3) and the following ones allow macroscopic properties like enthalpy and volume to be calculated from the thermal history of the glass.

At this point, one should inquire why the v_i coefficients are the same for H , V , and other macroscopic properties. As a matter of fact, whether the kinetics of H , V , or other macroscopic properties (e.g. refractive index) is related to one fictive temperature or to one set of fictive sub-temperatures has been debated extensively. With respect to all types of glass-forming systems, including polymers, the former alternative does not seem to be correct (as pointed out by, e.g. [12]), although the differences between the two are small (e.g. [13]). For silicate glasses, however, this universality seems to exist [14]. All examples given below do support this view that the kinetics of all macroscopic properties are related to a single fictive temperature or a single set of fictive sub-temperatures. To ensure a fair comparison of differently obtained kinetic data, an appropriate deconvolution of, e.g. DSC data has to be carried out (see Section 3.5).

Note that, the timescales of the vibrational and configurational responses to a jump in a state variable are essentially different. For an instantaneous temperature jump ΔT (at $t = 0$ for simplicity), there will first be an almost instantaneous change in vibrational states causing an enthalpy change $c_p^{\text{vib}} \Delta T$, followed by a time-dependent variation of the configurational state. The resulting enthalpy change is given by $c_p^{\text{conf}}(T_f(t) - T_f(0))$ at any time $t > 0$. The actual value of $T_f(t) - T_f(0)$ depends on kinetics. At some temperature below the glass transition range, the time to equilibrate vibrational and configurational degrees of freedom will become immeasurably long and $T_f(t) - T_f(0) = 0$ will hold on any realistic timescale. Only for $t \rightarrow \infty$ the system will eventually equilibrate and $T_f(\infty) - T_f(0) = \Delta T$ will hold.

Accordingly, the fictive temperature of a glass sample cooled from temperatures in or above the glass transition range to temperatures significantly below will reach an effectively final value that will not experience appreciable change on any realistic timescale (i.e. for $t < \infty$!). This value is called the glass transition temperature T_G . As T_G depends on the cooling rate, or more generally, the

thermal history, one may also define of T_G in a unique sense referring to the value obtained from glass linearly cooled at 2 K/min. It is determined by dilatometry according to ISO 7884-8 [15].

3.3 Tool's Original Model

The concept of fictive temperature as well as the first step toward a model of glass relaxation were proposed by Tool in 1946 [7] in terms of a structural relaxation time τ . The rate equation describing the kinetics of a single fictive temperature T_f was expressed with an Arrhenius-type *Ansatz* (approach)

$$\frac{dT_f}{dt} = \frac{T - T_f}{\tau}, \quad \tau = \tau_0 \cdot e^{H/R \cdot T} \quad (7)$$

where R is the gas constant. The basic ideas of this *Ansatz* are that:

- 1) the system tends to equilibrate, i.e. $T_f = T$, with a driving force given by the difference $T - T_f$.
- 2) the system is configurationally trapped in a *potential cage* where it vibrates at a frequency $\nu = 1/\tau_0$; a move toward another configuration then requires a jump over an enthalpy barrier H .

With these assumptions, H should be of the order of magnitude of the dissociation energy of a network, for example, that required to break all oxygen bridges. Since configurational rearrangements involve cooperative motion of numerous atoms rather than hopping of individual ones only, H is usually considerably higher than the enthalpy required for overcoming a microscopic barrier. For polymer glasses, H may actually exceed the dissociation energy of the C—C bond by half an order of magnitude [16].

Concerning ν , one is tempted to identify it with the Einstein frequency or another typical frequency of atomic vibrations. One finds, however, that the high values found for H have to be associated with either very high ν or very low τ_0 values to make, with Tool's formalism, the glass transition occur in the experimentally observed range, i.e. at several hundred rather than at several thousand degrees.

To assess the applicability of Eq. (7), one may have a glass equilibrate at a temperature T_0 first and then make a temperature jump from T_0 to T at $t = 0$. In that case, the fictive temperature for $t > 0$ is given by the differential Eq. (7) for constant temperature and for the initial condition $T_f(0) = T_0$. The solution is the well-known single-exponential relaxation function:

$$T_f = T + (T_0 - T) \cdot e^{-t/\tau} \quad (8)$$

However, more sophisticated approaches have had to be developed, since neither enthalpy nor volume relaxation conforms to such a simple solution.

3.4 The Tool–Narayanaswamy–Moynihan Model

This model is commonly known as Tool–Narayanaswamy or Tool–Narayanaswamy–Moynihan since its nonlinear character was dealt with by Narayanaswamy [17] and Moynihan [18]. As Mazurin, Rekhson, and Startsev had independently come to the same results [19] and as Kohlrausch-type kinetics had been introduced by Mazurin and Rekhson [20], it is appropriate to follow Hodge's [21] suggestion and term it Tool–Narayanaswamy–Moynihan(–Mazurin–Rekhson–Startsev), or TNM(MRS) model for short. Two main facts have motivated its introduction:

- 1) The configurational response of enthalpy or volume (or any other macroscopic property) to a temperature jump after equilibration is not by a single but by a stretched exponential, i.e. H or V (or another property) approximately follow a so-called Kohlrausch(–Williams–Watts)–function $\exp[-(t/\tau)^b]$, $0 < b < 1$ [22, 23] as also does a calculated fictive temperature (Figure 3).
- 2) Particularly for large temperature jumps, one observes an asymmetry between the upward and downward temperature jumps to the same final temperature. If prior equilibration was at a higher temperature, relaxation is faster and vice versa. The famous density relaxation experiments by Hara and Suetoshi [24] illustrate this behavior (Figure 4).

Figure 3 Single exponential $\exp(-t/\tau)$ versus stretched exponential $\exp(-(t/\tau)^b)$, $b = 0.3$. $H(t \downarrow 0)$, $V(t \downarrow 0)$ denote the values H , V take after the instantaneous vibrational response to the temperature jump, i.e. only the time-dependent configurational response is shown.

Figure 4 Density measurements of Hara and Suetoshi on soda-lime-glass during annealing at 530 °C.

These two facts are allowed for by the TNM(MRS) model in the following way:

- 1) The configurational state of a glass is described by a distribution of fictive sub-temperatures rather than by a single fictive temperature. By *fictive temperature*, without any further index, a weighted mean of the fictive sub-temperatures as defined in (5) is implied:

$$T_f(t) = \sum_{i=1}^n v_i \cdot T_{f,i}(t), \quad \sum_{i=1}^n v_i = 1 \quad (9)$$

- 2) All fictive sub-temperatures follow from the same type of differential equation as Tool's original one:

$$\frac{dT_{f,i}}{dt} = \frac{T - T_{f,i}}{\tau_i} \quad (10)$$

- 3) As a consequence, the isothermal relaxation of every fictive sub-temperature upon a temperature jump can be represented by a single-exponential (approximately, if ΔT is not too large, see below).
- 4) The coefficients v_i , relaxation times τ_i , and number n of fictive sub-temperatures are chosen such that the Kohlrausch-type response of the fictive temperature is best reproduced by the corresponding series of fictive sub-temperatures with single-exponential relaxation ("Prony-series"; with n given, the v_i and τ_i are found by an appropriate optimization routine):

$$\begin{aligned} T_f(t) &= T + (T_f(0) - T) \cdot e^{-(t/\tau)^b} \\ &= T + (T_f(0) - T) \cdot \sum_{i=1}^n v_i \cdot e^{-(t/\tau_i)} \\ &\equiv \sum_{i=1}^n v_i \cdot \left[T + (T_f(0) - T) \cdot e^{-(t/\tau_i)} \right] \\ &=: \sum_{i=1}^n v_i \cdot T_{f,i}(t) \end{aligned} \quad (11)$$

On the assumption of thermorheologic simplicity, b and, as a consequence, all v_i and quotients τ_i/τ are assumed independent of temperature.

- 5) The asymmetry of upward and downward temperature jumps is allowed for by the following modification of the thermal activation term:

$$\tau_i = \tau_{0,i} \cdot e^{(H/R) \cdot (x/T + (1-x)/T_f)} \quad (12)$$

where x is the so-called nonlinearity parameter that ranges from 0 to 1. If $x = 1$, Arrhenius behavior is obtained whereas $x < 1$ means that thermal activation is faster than with Arrhenius for $T_f > T$ and slower for $T_f < T$. In Eq. (12), T_f is the weighted mean from (9).

The deviation from Arrhenius-type thermal activation causes the differing forms of relaxation functions for small and large temperature jumps for which there is, or there is no, significant difference between Eq. (12) and $\exp(H/RT)$, respectively. As a consequence, the solutions to Eq. (10) are not single exponentials for large temperature jumps.

3.5 Calorimetric Determination of the TNM(MRS) Model Parameters

Differential scanning calorimetry [25] is a convenient technique to determine relaxation parameters (Figure 5). One measures the heat flux dH into a sample heated at ambient pressure and at constant rate dT/dt , which is commonly identified with $c_p^{\text{app}} \cdot dT$. Here, “apparent” means that any possible glass transition or crystallization is deliberately ignored. With respect to Eq. (6), one obtains:

$$c_p^{\text{app}} \frac{dT}{dt} := \frac{dH}{dt} = c_p^{\text{vib}} \frac{dT}{dt} + c_p^{\text{conf}} \frac{dT_f}{dt}. \quad (13)$$

Below the glass transition, the measured c_p values are purely vibrational whereas above it, they are also configurational. To distinguish between both contributions,

one may extrapolate c_p from below to above the glass transition with, for instance, the Einstein model and the Dulong–Petit-value as a high-temperature limit of c_p^{vib} .

In the glass transition range, the rapid variations of c_p^{app} reflect the fictive temperature(s) kinetics upon heating at a constant rate. From an analysis of this peak, the parameters of the TNM(MRS) model may be determined [26]. The procedure is as follows. From Eq. (13), one obtains:

$$\frac{dT_f}{dt} = \frac{c_p^{\text{app}} - c_p^{\text{vib}}}{c_p^{\text{conf}}} \cdot \frac{dT}{dt} \quad (14)$$

In an optimization routine, one calculates the left side of Eq. (14) from Eqs. (9), (10), and (12) and equates it to the right side by varying the parameters H , τ_0 , b , and x . In the first step of every optimization loop, a set of v_i and τ_i is calculated according to the optimization procedure already described with Eq. (11). The number n indicating the length of the “Prony Series” is individually picked and should be “sufficiently high.” In the example below, a value $n = 10$ is used.

To make sure that the parameters obtained from DSC are real and not adversely affected by unavoidable noise in the data, it is recommended to identify features like *peak width*, *peak-to-peak distance*, etc., that are very sensitive to a single parameter. One scan does not provide enough different features but two at different heating rates are in principle fine. These features are the position of the inflection point of the simulated c_p^{app} versus T curve, the width of the calorimetric glass transition, the shift of said inflection point with the heating rate, and the asymmetry of the glass transition, which are most sensitive to the parameters τ_0 , b , H/R , and x , respectively (Figure 6). Of course, an appropriate deconvolution of the DSC data is a prerequisite for achieving an excellent agreement between the calculated and experimental thermogram [27, 28].

Figure 5 Typical DSC of an “optically” (i.e. slowly) cooled BK7 sample. Heating rate 12 K/min. Data as measured (no deconvolution). Measurement by SETARAM Multi-HTC 96® at the accredited laboratories of SCHOTT AG.

Figure 6 (a–h) Subsequent adjustment of the TNM(MRS) model parameters τ_0 , b , H/k , and x (adjustment of the latter not shown here) in order to make the simulated dT_f/dT curves (dashed lines) overlap with those obtained from measurement on BK7 (solid lines).

3.6 Prediction of Thermal Shrinkage with the TNM(MRS) Model

Once the parameters of the TNM(MRS) model are known, their predictive power can be ascertained from comparisons made between observed and calculated thermal shrinkage (Figure 7). In other words, the calorimetric TNM(MRS) parameters will be applied here to volume measurements. In these experiments, a temperature jump is simply realized through the transfer of a sample equilibrated in an oven at a given temperature to another oven at a different temperature. The glass can then be repeatedly removed from the latter at different times for length measurements at room temperature without any spurious influence of a dilatometer push rod. Provided that α^{conf} is known from a density measurement in the molten state, comparison of the measured values with TNM(MRS)-based calculations may be made without any fit parameter from

$$\frac{l(t) - l(t \downarrow 0)}{l(t \downarrow 0)} \equiv \frac{\Delta l}{l} = \alpha^{\text{conf}} \cdot (T_f(t) - T_f(0)). \quad (15)$$

Here on the left side is the relative shrinkage of the sample (as calculated from the measured sample length after a temperature jump at $t = 0$, the immediate response of the sample at $t = 0$ being discarded); and on the right side is the difference of the fictive temperatures at times t and 0.

Note that whereas these paragraphs deal with BK7®, similar recent investigations at Clemson University [29, 30] have dealt with the new glass N-BK7®.

3.7 Prediction of Refractive Index with the TNM (MRS) Model

The predictive power of the “calorimetric” TNM(MRS) model can again be demonstrated for an “optical”

Figure 7 Comparison of a thermal shrinkage experiment on BK7 (solid line) with values calculated by the TNM(MRS) model (dashed line) with the parameters τ_0 , b , H/k , and x determined above and $\alpha^{\text{conf}} = 37$ ppm/K determined from a density versus temperature measurement in the molten stage. Measurement at the accredited laboratories of SCHOTT AG.

property, namely the refractive index with its dependence on a linear cooling rate [31]. Provided that the eigenfrequencies of the electron oscillators do not depend on thermal history, the refractive index is a function of density only, which in turn is a function of the fictive temperature. The room-temperature value of the latter depends on the cooling rate $q = dT/dt$. Therefore, one may write:

$$n(\lambda, q) = n(\lambda)_{\text{ref}} + \frac{\partial n(\lambda)}{\partial T_f} (T_f(q) - T_{f,\text{ref}}) \quad (16)$$

where λ is the wavelength, $\partial n/\partial T_f$ is assumed to be a constant, and “ref” refers to a reference state defined, for instance, by a standard cooling rate.

With the parameters of the TNM(MRS) model known from DSC and $\partial n/\partial T_f$ from an additional temperature-jump experiment, one may calculate $n(\lambda, q)$ from the reference value $n(\lambda)_{\text{ref}}$. For sake of simplicity, one may use an empirical linear relation from Moynihan and coworkers, which links the final fictive temperature and the logarithm of the cooling rate [18]:

$$\frac{H}{RT_{f,1}} - \frac{H}{RT_{f,2}} = \ln \left(\frac{q_2}{q_1} \right) \quad (17)$$

where $T_{f,1,2}$ is the fictive temperature upon linear cooling at a rate $q_{2,1}$. Although (17) has not yet been rigorously derived, it is widely applied because it condenses the essential result of the TNM(MRS) model in the case of linear cooling. Inserting (17) into (16) leads to:

$$n(\lambda, q) = n(\lambda)_{\text{ref}} + \frac{\partial n(\lambda)}{\partial T_f} \frac{T_f(q) T_{f,\text{ref}}}{H/R} \ln \left(\frac{q}{q_{\text{ref}}} \right) \quad (18)$$

For an approximation and further simplification, one may replace $T_f(q)$ and $T_{f,\text{ref}}$ with the T_G value according to [15]:

$$n(\lambda, q) = n(\lambda)_{\text{ref}} + \frac{\partial n(\lambda)}{\partial T_f} \frac{T_G^2}{H/R} \ln \left(\frac{q}{q_{\text{ref}}} \right) \quad (19)$$

Thus, the above-mentioned logarithmic relationship between the refractive index and the cooling rate may be derived from relaxation dynamics.

To calculate numbers, $\partial n/\partial T_f$, T_G , and H/R have to be known from the above-mentioned experiments ($\partial n/\partial T_f$ by V block refractometer measurement after annealing at different temperatures, i.e. by a temperature jump experiment; T_G , by dilatometry; H/R , by DSC plus data reduction according to the TNM(MRS) model). An overview of glass characterization methods is provided by [32]. The refractive index considered is n_d , i.e. the one at the helium d-line, 587.6 nm. For the crown glass P-SK57® and the flint glass P-LaSF47®, the values are given in Table 1 [31]. (N.B. For *crown* and *flint* glasses, see [33] and chapters 6.1 and 10.9).

Table 1 Properties of glasses P-SK57[®] and P-LaSF47[®].

Glass	$T_g/^\circ\text{C}$	$(\partial n_d/\partial T_g)/(1/\text{K})$	$(H/R)/\text{K}$
P-SK57 [®]	493	0.000 067 2	84 396.5
P-LaSF47 [®]	530	0.000 117	103 154

Table 2 Calculated versus measured refractive index values for glasses P-SK57[®] and P-LaSF47[®].

Glass	Cooling rate/ (K/h)	n_d (measured)	n_d (calculated)
P-SK57 [®]	2 (reference)	1.587 00	—
	9.5	1.586 26	1.586 27
	47	1.585 56	1.585 52
	236	1.584 85	1.584 77
P-LaSF47 [®]	2 (reference)	1.806 10	—
	9.6	1.805 03	1.804 95
	47	1.803 98	1.803 79
	230	1.802 89	1.802 63

With the values from Table 1, one may calculate the refractive indices for different cooling rates and compare them with the measured ones, as provided in Table 2. Between the measured and the calculated values, one finds a maximum difference $<10^{-4}$ for glasses P-SK57[®] and $<3 \cdot 10^{-4}$ P-LaSF47[®], which is satisfactory with respect to the multiple error sources involved (temperature determination in the temperature jump experiment, calibration of the DSC, etc.).

4 Shear Viscoelasticity

Essentially, there are two orthogonal ways to deform a material, i.e. either at constant volume or at constant shape. Therefore, two types of viscoelasticity thus have to be dealt with. The first to be considered is the former, i.e. the response to shear stress.

4.1 Maxwell Model

If suddenly exposed to constant shear strain in the glass transition range, the glass will initially respond with elastic shear stresses, which will then decrease with time because of relaxation. As a consequence, the applied loads that maintain the constant shear strain will relax. If exposed to constant shear stress, the opposite will

**Figure 8** Maxwell model for viscoelasticity: spring in series with a dashpot (piston moving in a hollow cylinder filled with a viscous fluid). z_1 and z_2 , displacements of spring/piston; z , total displacement; $F_1 = F_2 = F$, force measured along the setup.

occur. In this case the glass will initially respond with an elastic shear strain, which in time will become a combination of the instantaneous response and a continuous elongation, which is referred to as creep. Maxwell has described these features by a model consisting of a spring and a dashpot in a series. Such a combination of an elastic response on short timescales and a viscous one on long timescales is called viscoelasticity [34a] (Figure 8).

For Maxwell's model and a continuously increasing elongation caused by a constant force F applied for $t \geq 0$, the following equation holds:

$$z = \frac{F}{D} + \frac{F}{\eta \cdot \frac{A}{d}} \cdot t \quad (20)$$

where D is the spring constant, η the viscosity, A both the outer surface of the piston and the inner surface of its hollow cylinder, and d the distance between the piston and hollow cylinder.

This equation may be derived with the following intermediary steps:

$$\begin{aligned} F_1 &= D \cdot z_1 \\ F_2 &= \eta \cdot \frac{A}{d} \cdot \frac{dz_2}{dt} \\ F_1 &= F_2 = F \\ z_1 + z_2 &= z \end{aligned} \quad (21)$$

The transition from elastic to viscous deformation occurs abruptly in this simplest case. In an infinitesimally short time, the elastic energy $\frac{1}{2}F^2/D$ accumulates in the spring and will be conserved for the rest of the time; the further energy transferred to the system will be completely dissipated.

Actual viscoelastic relaxation is observed if a constant elongation z is imposed. In this case, the force F required to maintain the elongation is:

$$F(t) = D \cdot \text{const} \cdot e^{-t \cdot (D \cdot d)/(\eta \cdot A)} = D \cdot \text{const} \cdot e^{-t/\tau} \quad (22)$$

The time constant $\tau = (A \cdot \eta)/(D \cdot d)$ is the relaxation time. Equation (22) may be derived with the following intermediary steps:

$$\begin{aligned}
\frac{dz_1}{dt} + \frac{dz_2}{dt} &= 0 \\
\frac{1}{D} \cdot \frac{dF_1}{dt} + \frac{d}{A} \cdot \frac{F_2}{\eta} &= 0 \\
F_1 &= F_2 = F
\end{aligned} \quad (23)$$

This time there is no further energy transfer to the system after the initial one. The elastic energy $\frac{1}{2}F^2/D$ accumulated in the spring at the beginning will not be conserved but will be dissipated completely in the dashpot during relaxation.

4.2 (Kelvin-)Voigt Model: Delayed Elasticity

For a more realistic description of viscoelasticity, delayed elasticity must also be taken into account. It may be represented by a (Kelvin-)Voigt model, which responds like a rigid body on a short timescale and like an elastic body on long timescales. The (Kelvin-)Voigt model consists of a spring and dashpot set up in parallel [34b] (Figure 9). For a constant force, the response is:

$$z = \frac{F}{D} \cdot \left(1 - e^{-t \cdot (d \cdot D)/(A \cdot \eta)}\right) \quad (24)$$

where the time constant involved is called retardation time. Equation (24) may be derived with the following intermediate steps:

$$\begin{aligned}
F_1 &= D \cdot z_1 \\
F_2 &= \eta \cdot \frac{A}{d} \cdot \frac{dz_2}{dt} \\
z_1 &= z_2 = z \\
F &= F_1 + F_2
\end{aligned} \quad (25)$$

From Eq. (25), one derives the following inhomogeneous differential equation that may be solved by the *variation of the constant*,

$$D \cdot z + \eta \cdot \frac{A}{d} \cdot \frac{dz}{dt} = F. \quad (26)$$

which leads to (24).

The case of an instantaneous, fixed elongation may not be simulated with a Voigt model.

Figure 9 Voigt model for viscoelasticity: spring in parallel to a dashpot. $z_1 = z_2 = z$, displacement; F_1 , force measured at spring; F_2 , force measured at dashpot; F , total force measured.

4.3 Shear in Glass

When one considers a volume element under shear stress, the link between the glass response and that of the previous models is found by a transformation from force (elongation) to stress (strain) (Figure 10) as follows:

$$F_1 = D \cdot z_1 \rightarrow \sigma_1 = G \cdot \epsilon'_1 \quad (27)$$

$$F_2 = \eta \cdot \frac{A}{d} \cdot \frac{dz_2}{dt} \rightarrow \sigma_2 = \eta \cdot \frac{d\epsilon'_2}{dt} \quad (28)$$

where ϵ' is the amount by which the angle γ' changes. The quantity γ' in return is the change in angle between those two edges of the (previously cubic) volume element that are perpendicular to the shear axis.

Commonly, however, it is not ϵ' which is used to describe the deformation of the volume element, but the value ϵ which describes the change of the angle γ . γ is the angle between either of the above edges and the diagonal between them. As $\epsilon = \epsilon'/2$, one has to introduce a factor of 2 for compensation.

$$F_1 = D \cdot x \rightarrow \sigma_1 = G \cdot 2 \cdot \epsilon_1 \quad (29)$$

$$F_2 = \eta \cdot \frac{A}{d} \cdot \frac{dz_2}{dt} \rightarrow \sigma_2 = \eta \cdot 2 \cdot \frac{d\epsilon_2}{dt} \quad (30)$$

The simple Maxwell model allows an illustration of what is observed in glass

- 1) as short-term and long-term response to an imposed constant shear stress σ_0 :

$$\epsilon = \frac{\sigma_0}{2G} + \frac{\sigma_0}{2\eta} \cdot t = \left(\frac{1}{2G} + \frac{t}{2\eta}\right) \cdot \sigma_0 =: J(t) \cdot \sigma_0 \quad (31)$$

where $J(t)$ is the *compliance*,

the first term, i.e. $\sigma_0/(2G)$, describes the instantaneous response by the glass, which corresponds to the response of the spring in the simple Maxwell model; the second term, i.e. $\sigma_0/(2\eta)$, describes the continuous and constant deformation of the glass by creep, which corresponds to the response of the dashpot in the simple Maxwell model.

Figure 10 Definition of shear angle ϵ .

2) as response to a constant shear strain ε_0 :

$$\begin{aligned}\sigma(t) &= 2 \cdot G \cdot \varepsilon_0 \cdot e^{-t \cdot (G/\eta)} \\ &= (2 \cdot G \cdot e^{-t \cdot (G/\eta)}) \cdot \varepsilon_0 =: (2 \cdot G \cdot e^{-t/\tau}) \cdot \varepsilon_0 \\ &=: G(t) \cdot \varepsilon_0\end{aligned}\quad (32)$$

where $\tau = \eta/G$ is the relaxation time and $G(t)$ the time-dependent shear modulus (note $G(t) := 2 \cdot G \cdot e^{-t/\tau}$); the value $\sigma(0)$ describes the instantaneous response of the glass to the strain that is imposed at $t = 0$. So $\sigma(0)$ corresponds to the elastic response of the spring in the simple Maxwell model at $t = 0$ when the whole elongation is with the spring. The exponential decrease of $\sigma(t)$ describes the subsequent stress relaxation in the glass, which corresponds to the stress release in the spring when a rising fraction of the elongation is with the dashpot for $t > 0$.

The simple Voigt model allows the illustration of a delayed elastic response to constant shear stress:

$$\begin{aligned}\varepsilon &= \frac{\sigma_0}{2G} \cdot \left(1 - e^{-t \cdot (G/\eta)}\right) \\ &= \left(\frac{1}{2G} \cdot \left(1 - e^{-t \cdot (G/\eta)}\right)\right) \cdot \sigma_0 \\ &=: \left(\frac{1}{2G} \cdot \left(1 - e^{-t/\tau}\right)\right) \cdot \sigma_0 =: J(t) \cdot \sigma_0\end{aligned}\quad (33)$$

where $\tau = \eta/G$ is the retardation time and $J(t)$ again is the compliance. The delayed elastic response of the glass, i.e. a second elastic deformation gradually building up after the first, instantaneous elastic deformation, corresponds to the stress, which builds up in the spring of the simple Voigt model when the piston in the dashpot starts to move.

4.4 A Realistic Representation of Shear Relaxation: Burger Model

As shear relaxation of inorganic glasses cannot be described with either the Maxwell or the Voigt model alone (Figure 11), a better representation is provided by a combination of the two in series known as the Burger model [34c] (Figure 12). At constant stress, the strain is:

$$\begin{aligned}\varepsilon &= \left[\frac{1}{2G_2} + \frac{t}{2\eta_2} + \left(\frac{1}{2G_1} \cdot \left(1 - e^{-t \cdot (G_1/\eta_1)}\right) \right) \right] \cdot \sigma_0 \\ &=: J_{\text{Burger}}(t) \cdot \sigma_0\end{aligned}\quad (34)$$

The first term thus represents the instantaneous response, the second long-term creep, and the third delayed elasticity. At constant strain, the stress then is:

Figure 11 Typical time-dependent response of glass to constant shear stress. Essentially, there are phases. First, an instantaneous and reversible (i.e. elastic) strain response (1) when the shear stress is imposed at $t = 0$. Second, a transition phase involving both a reversible (i.e. elastic), however delayed strain contribution (2) plus an irreversible creep contribution (3). Third, pure creep (4).

Figure 12 Burger model.

$$\sigma = \frac{2 \cdot G_2 \cdot \varepsilon_0}{(\lambda_+ - \lambda_-)} \cdot \left[\left(\lambda_+ + \frac{G_1}{\eta_1} \right) \cdot e^{\lambda_+ \cdot t} + \left(-\lambda_- - \frac{G_1}{\eta_1} \right) \cdot e^{\lambda_- \cdot t} \right] \quad (35)$$

This case is mathematically more complicated because the parameters λ_+ , λ_- are the roots of the equation $G_1 \cdot G_2 + (G_2 \cdot \eta_2 + G_1 \cdot \eta_2 + G_2 \cdot \eta_1) \cdot \lambda + \eta_1 \cdot \eta_2 \cdot \lambda^2 = 0$. See [34] or [35] for the derivations. Because λ_+ and λ_- are negative numbers, one may alternatively write:

$$\sigma = 2 \cdot G_2 \cdot \varepsilon_0 \cdot \left[v_1 \cdot e^{-t/\tau_1} + v_2 \cdot e^{-t/\tau_2} \right] \quad (36)$$

where τ_1 and τ_2 are relaxation times and v_1 and v_2 coefficients fulfilling the condition $v_1 + v_2 = 1$. As λ_+ is a small negative number compared with G_1/η_1 and λ_- is a large negative number compared with G_1/η_1 , both $v_1 = (\lambda_+ + G_1/\eta_1)/(\lambda_+ - \lambda_-)$ and $v_2 = (\lambda_- + G_1/\eta_1)/(\lambda_+ - \lambda_-)$ are positive numbers.

Thus, Eq. (35) or (36) is an analog of (32) with the difference that a single exponential relaxation in Eq. (32) has been replaced by a double exponential with two relaxation times.

As it will be shown below, the single exponential will be replaced with a whole spectrum of relaxation times in the general case.

4.5 Kohlrausch (Williams–Watts) Kinetics for Shear Relaxation

As for structural relaxation, replacement of single exponential functions with a stretched exponential or Kohlrausch(–Williams–Watts)-function is required to match the experimental data [8b] (Figure 13). For constant stress, the strain becomes:

$$\varepsilon = \left[\frac{1}{2G_0} + \frac{t}{2\eta} + \left(\frac{1}{2G_\infty} - \frac{1}{2G_0} \right) \cdot \left(1 - e^{-(t/\tau)^b} \right) \right] \cdot \sigma_0$$

$$=: J(t) \cdot \sigma_0 \quad (37)$$

where $1/(2G_0)$ represents the instantaneous elastic response, $1/(2G_\infty)$ the sum of the instantaneous and delayed elastic response, and $t/(2\eta)$ long-term creep. As above $J(t)$ is the time-dependent compliance and τ is a retardation time. By construction, this expression resembles very much that of the Burger model, with the exception of the kinetics of delayed elasticity. For computational purposes, the Kohlrausch function may be represented by a number of single exponentials (Prony-series) [8b]:

$$\varepsilon = \left[\frac{1}{2G_0} + \frac{t}{2\eta} + \left(\frac{1}{2G_\infty} - \frac{1}{2G_0} \right) \cdot \sum_i v_i \cdot \left(1 - e^{-t/\tau_i} \right) \right] \cdot \sigma_0$$

$$=: J(t) \cdot \sigma_0, \quad \sum_i v_i = 1 \quad (38)$$

For constant strain, the switch to Kohlrausch kinetics yields for the stress:

$$\sigma(t) = 2 \cdot G \cdot \varepsilon_0 \cdot e^{-(t/\tau)^b} =: G(t) \cdot \varepsilon_0 \quad (39)$$

where $G(t)$ is the time-dependent modulus and τ is the a relaxation time. Again, the Kohlrausch-function may be

Figure 13 Single exponential function $\exp(-t/\tau)$ versus Kohlrausch (–Williams–Watts) or stretched exponential function $\exp(-(t/\tau)^b)$, $b = 0.3$.

represented by a number of single exponentials (Prony-series):

$$\sigma(t) = 2 \cdot G \cdot \varepsilon_0 \cdot \sum_i v_i \cdot \left(1 - e^{-t/\tau_i} \right) =: G(t) \cdot \varepsilon_0 \quad (40)$$

4.6 Boltzmann's Superposition Principle

In general, i.e. not only for shear, it is assumed that the stress effects arising from strain contributions imposed at different times add up without mutual interference [34d]:

$$\sigma(t) = 2 \cdot G \cdot \sum \Delta \varepsilon_{(\text{at time } t')} e^{-((t-t')/\tau)^b}$$

$$\approx 2 \cdot G \cdot \int_{-\infty}^t e^{-((t-t')/\tau)^b} \cdot \frac{d\varepsilon(t')}{dt'} \cdot dt' \quad (41)$$

4.7 Temperature Dependence of the Relaxation Time

Over the small width of the glass transition range it is legitimate to use an Arrhenius Ansatz for the temperature dependence of the shear viscosity [8c]:

$$\eta = \eta_0 e^{H/R \cdot T} \quad (42)$$

With the assumption of a constant shear modulus, the shear relaxation time of the Maxwell model [8d] then varies in the same way with temperature:

$$\tau = \tau_0 e^{H/R \cdot T} \quad (43)$$

For the present viscoelastic model, one follows this Ansatz for the relaxation or retardation times of Eqs. (37) and (39) by considering not only G_0 and G_∞ but also the b parameter to be constant (thermorheologic simplicity). Further, if one assumes that Eq. (43) can be extended to the nonequilibrium case as done with the corresponding formula (12) for structural relaxation, one obtains [8e]:

$$\tau = \tau_0 \cdot e^{(H/R) \cdot (x/T + (1-x)/T_f)} \quad (44)$$

Even further, if one assumes that both the activation enthalpy H and the nonlinearity parameter x are the same for structural and shear relaxation, the fictive temperature T_f is the same as defined in Eq. (9).

For nonequilibrium calculations with varying temperatures and fictive temperatures, one must convert these expressions into differential equations by calculating time

derivatives of both sides. Preferably, one chooses Prony-series representations as starting points.

4.8 Determination of the Parameters of Shear Viscoelasticity

The parameters may be determined from the phase shift between the force and the elongation during an oscillating load (Figure 14) in mechanical spectroscopy experiments made by dynamic mechanical analysis (DMA) [34e, 35]. The starting point is the time dependence of strain and stress:

$$\varepsilon(t) = \varepsilon_0 \cdot \cos(\omega t), \quad \omega = 2\pi \cdot \nu, \quad \text{or} \quad \varepsilon(t) = \varepsilon_0 \cdot e^{i\omega t} \quad (45)$$

$$\Rightarrow \sigma(t) = 2 \cdot G \cdot i \cdot \omega \cdot \varepsilon_0 \cdot e^{i\omega t} \cdot \int_0^\infty e^{-(t''/\tau)^b} \cdot e^{-i\omega t''} \cdot dt'' \quad (46)$$

With Boltzmann's superposition principle, one obtains for the stress

$$\sigma(t) = \left[2 \cdot G \cdot i \cdot \omega \cdot \int_0^\infty e^{-(t''/\tau)^b} \cdot e^{-i\omega t''} \cdot dt'' \right] \cdot \varepsilon_0 \cdot e^{i\omega t} \quad (47)$$

The term in brackets is called the complex modulus. Introducing the phase shift δ between stress and strain, one obtains:

$$\sigma = \omega \cdot 2 \cdot G_0 \cdot \varepsilon_0 \cdot e^{i\omega t} \cdot e^{i\delta} \quad (48)$$

with

$$\tan(\delta) = \int_0^\infty e^{-(y/\tau)^b} \cdot \cos(\omega y) \cdot dy / \int_0^\infty e^{-(y/\tau)^b} \cdot \sin(\omega y) \cdot dy \quad (49)$$

Owing to the lack of analytic solution, τ and b must in general be determined numerically. Within the glass transition range, however, τ is of the order of 10s so that the following approximation is very good for frequencies higher than 1 Hz [35, 36].

Figure 14 Oscillating shear.

$$\tan(\delta) = \frac{\Gamma(1+b)}{(\omega\tau)^b} \sin\left(\frac{\pi b}{2}\right) + O\left(1/(\omega\tau)^{2b}\right) \quad (50)$$

A higher order analysis leads to:

$$\begin{aligned} \tan(\delta) = & \frac{\Gamma(1+b)}{(\omega\tau)^b} \sin\left(\frac{\pi b}{2}\right) \\ & + \frac{((\Gamma(1+b))^2 - \Gamma(1+2b))}{2(\omega\tau)^{2b}} \sin(\pi b) + O\left(1/(\omega\tau)^{3b}\right) \end{aligned} \quad (51)$$

If $\tan(\delta)$ is known as a function of frequency from DMA, both τ and b may be determined via Eq. (51) with an imprecision of 1 and 2% for $\tan(\delta)$ values lower than 0.17 and 0.24, respectively. If one varies the temperature as well, H can also be obtained. See [35] for the derivation of (50, 51).

An approximate, but simple way to impose shear – either in a static or in a dynamic way – is by bending.

For three-point-bending of thin samples (Figure 15), the elongation s arising from a force F is [37]:

$$s = F \cdot \frac{l^3}{4 \cdot E \cdot d \cdot h^3} \propto \frac{1}{E} \quad (52)$$

With typical values for glass, i.e. $E = 60$ GPa and $\nu = 0.2$ [38], and

$$G = \frac{E}{2(1+\nu)}, \quad K = \frac{E}{3(1-2\nu)}, \quad \frac{1}{E} = \frac{1}{3G} + \frac{1}{9K} \quad (53)$$

one arrives at the fact that about 80% of the elongation is due to shear and only the remaining 20% to compression/dilatation. This ratio may even be increased by a Finite-Element-optimized asymmetric four-point-bending [35, 39, 40] (Figure 16). For $a = 8$ mm, $b = 16$ mm, $c = 6$ mm, $h = 4$ mm, about 86% of the elongation is due to shear.

A typical measurement of this type is carried out by varying both frequency and temperature so that all three parameters τ_0 , b , and H may be determined. (The data set taken for parameter evaluation is limited to data from

Figure 15 Three-point-bending.

Figure 16 Asymmetric four-point-bending.

above the glass transition range so that equilibrium can be assumed.) Figure 17 shows a DMA on Borofloat33®.

Note that in addition to the dynamic experiments described here, shear relaxation parameters may also be derived from creep measurements, e.g. the ones that have been carried out at Clemson University [41, 42].

5 Bulk Viscoelasticity

Shape-conserving deformation in response to pressure changes is now considered. With respect to shear deformation, the main difference is that the density changes and, consequently, also all other intensive properties.

Figure 17 DMA on Borofloat33 in the asymmetric four-point-bending mode ($a = 10$ mm, $b = 12$ mm, $c = 4$ mm, $h = 7$ mm; ratio of shear deformation to total deformation 0.82) leading to $b = 0.323$ 191, $H/R = 52$ 725.8 K, $\tau_0 = 2.256$ 44 · 10⁻²⁶ s. Measurement by GABO EPLEXOR® at the accredited laboratories of SCHOTT AG.

5.1 Bulk Viscoelasticity in Case of Small Pressure Changes

As long as the pressure change is small enough that relaxation properties do not vary significantly, bulk and shear viscoelasticity can be dealt with in a similar way. Consider a glass volume element under pressure (Figure 18). In analogy to (29, 30), but with a Voigt model as starting point, one obtains:

$$F_1 = D \cdot z \rightarrow p_1 = K \cdot 3 \cdot \varepsilon \quad (54)$$

$$F_2 = \eta_V \cdot \frac{A}{d} \cdot \frac{dz}{dt} \rightarrow p_2 = \eta_V \cdot \frac{d\varepsilon}{dt} \quad (55)$$

$$p = p_1 + p_2 \quad (56)$$

The factor 3 allows for the fact that the bulk modulus relates the stress to the strain in three dimensions. η_V is the second or bulk viscosity. Assuming constant pressure p_0 , the strain derived for the Voigt model is [8f]:

Figure 18 Deformation under pressure.

Figure 19 Series of a Voigt model and a spring.

$$\begin{aligned}\varepsilon &= \frac{p_0}{3K} \cdot \left(1 - e^{-t \cdot (3K/\eta_V)}\right) \\ &= \left(\frac{1}{3K} \cdot \left(1 - e^{-t \cdot (3K/\eta_V)}\right)\right) \cdot p_0 = J(t) \cdot p_0\end{aligned}\quad (57)$$

This simple model does not account for all the features observed upon compression of an inorganic glass under pressure. There are two effects, namely instantaneous and delayed strain. In contrast to shear, creep is not possible. Therefore, the simplest model suited is a Voigt model and a spring in series [8g] (Figure 19).

This model allows an illustration of what is observed in glass

- 1) as instantaneous and delayed response to an imposed pressure p_0 :

$$\begin{aligned}\varepsilon &= \left[\left(\frac{1}{3K_2}\right) + \left(\frac{1}{3K_1} \cdot \left(1 - e^{-t \cdot (3K_1/\eta_V)}\right)\right)\right] \cdot p_0 \\ &=: J(t) \cdot p_0\end{aligned}\quad (58)$$

with $J(t)$ being the thus defined compliance;

the first term, i.e. $p_0/(3K_2)$, describes the instantaneous response by the glass, which corresponds to the response of the single spring in the above model; the second term, i.e. $(p_0/(3K_1))(1 - e^{-t(3K_1/\eta_V)})$, describes the delayed response by the glass by creep, which corresponds to the Voigt model above.

- 2) as a partially relaxing response to an imposed strain ε_0 :

$$\begin{aligned}p(t) &= 3 \cdot K_2 \cdot \varepsilon_0 - \frac{3 \cdot K_2 \cdot K_2}{K_1 + K_2} \cdot \varepsilon_0 \cdot \\ &\quad \left(1 - e^{-t \cdot (3 \cdot (K_1 + K_2)/\eta_V)}\right); \end{aligned}\quad (59)$$

the first term, i.e. $3K_2\varepsilon_0$, describes the instantaneous response by the glass, which corresponds to the response of the single spring in the above model; the second term, i.e. $-(3K_2K_2/(K_1 + K_2))\varepsilon_0(1 - e^{-t(3(K_1 + K_2)/\eta_V)})$, describes the diminishment of a part of that response for $t > 0$ and corresponds to the Voigt model above. See [34] or [35] for the mathematical derivation.

Consider the difference between the retardation time $\tau = \eta_V/(3 \cdot K_1)$ and the relaxation time $\tau = \eta_V/(3 \cdot (K_1 + K_2))$.

Again, a better match of theoretical with experimental data is obtained if single exponential functions are replaced with stretched exponential or Kohlrausch(–Williams–Watts)–functions. We also replace K_1, K_2 by the better-suited set K_0, K_∞ (correspondence is obvious).

For constant stress, this gives:

$$\begin{aligned}\varepsilon &= \left[\frac{1}{3K_0} + \frac{1}{3} \left(\frac{1}{K_\infty} - \frac{1}{K_0}\right) \cdot \left(1 - e^{-(t/\tau)^b}\right)\right] \cdot p_0 \\ &=: J(t) \cdot p_0\end{aligned}\quad (60)$$

where $J(t)$ is the time-dependent compliance and τ the retardation time in this case. Again, a Prony series may be advantageous for computational purposes:

$$\begin{aligned}\varepsilon &= \left[\frac{1}{3K_0} + \frac{1}{3} \left(\frac{1}{K_\infty} - \frac{1}{K_0}\right) \cdot \sum_i v_i \cdot \left(1 - e^{-t/\tau_i}\right)\right] \cdot p_0 \\ &=: J(t) \cdot p_0, \quad \sum_i v_i = 1\end{aligned}\quad (61)$$

The expression for constant strain is:

$$\begin{aligned}p(t) &= \left[3 \cdot K_\infty + (3 \cdot K_0 - 3 \cdot K_\infty) \cdot e^{-(t/\tau)^b}\right] \cdot \varepsilon_0 \\ &=: K(t) \cdot \varepsilon_0\end{aligned}\quad (62)$$

where τ is now the relaxation time and $K(t)$ the time-dependent modulus. With a Prony series, this reads:

$$\begin{aligned}p(t) &= \left[3 \cdot K_\infty + (3 \cdot K_0 - 3 \cdot K_\infty) \cdot \sum_i v_i \cdot \left(1 - e^{-t/\tau_i}\right)\right] \cdot \varepsilon_0 \\ &=: K(t) \cdot \varepsilon_0, \quad \sum_i v_i = 1\end{aligned}\quad (63)$$

Concerning the temperature dependence, the assumptions are the same as made above for shear viscoelasticity in that K_0 and K_∞ are considered constant. Likewise, b is considered not to depend on temperature (assumption of thermorheologic simplicity). It is further assumed that the activation enthalpy of bulk relaxation is the same as for shear stress [8h] as well as for structural relaxation and that the same holds for the nonlinearity parameter x so that the relaxation time is given by:

$$\tau = \tau_0 \cdot e^{(H/R) \cdot (x/T + (1-x)/T_f)} \quad (64)$$

where the fictive temperature T_f is the same as defined as in Eq. (9).

For nonequilibrium calculations (varying temperature, varying fictive temperature), one must again convert

these expressions into differential equations by calculating the time derivative of both sides. Once more, one preferably chooses Prony-series representations as starting points.

5.2 Bulk Viscoelasticity for Large Pressure Changes – Fictive Pressure

As described by Eq. (60), the response of a glass to a constant pressure p_0 is both immediate ($p_0/3K_0$) and delayed, with a final value $p_0 \cdot (1/3K_\infty - 1/3K_0)$. The latter can be interpreted as the impact of a second, fictive pressure P_f , with an initially zero value, a final value p_0 , and an intermediate behavior described by unity minus a Kohlrausch function. One then rewrites Eq. (60) as:

$$\varepsilon = \frac{1}{3K_0} \cdot p_0 + \frac{1}{3} \left(\frac{1}{K_\infty} - \frac{1}{K_0} \right) \cdot p_f, \quad (65)$$

$$p_f = p_0 \left(1 - e^{-(t/\tau)^b} \right)$$

Owing to the temperature dependence of the retardation time τ , the fictive pressure is maintained when p_0 is removed after cooling to room temperature. The term $p_f(1/3K_\infty - 1/3K_0)$ may then be used as a measure of permanent densification.

At pressures high enough that the energy pV_m is similar to or higher than RT (V_m , molar volume), the pressure and fictive pressure dependences of the retardation time must also be taken into account. With the TNM(MRS) Ansatz, one obtains for the isothermal case [43]:

$$\tau = \tau_0 \cdot e^{H/RT} \cdot e^{[(p \cdot x' \cdot V^*/RT) + (p_f \cdot (1-x') \cdot V^*/RT)]} \quad (66)$$

i.e. a modified version of the original expression in [43] formulated to ensure that the equilibrium value of τ from the original TNM model follows for $p = 0$. As an analog of the activation enthalpy, V^* is called the activation volume [44] whereas x' is the analog of the nonlinearity parameter x .

6 Perspectives

The linear thermo-viscoelastic theory of relaxation [8, 34], see also as presented here has been extremely successful in applied glass science, see, e.g. [45]. There are shortcomings, however, which demand further research not only from a scientific but also from a glass practitioner's point of view. Three of them shall be shortly discussed here.

The first issue is the essentially non-Arrhenian temperature dependence of relaxation times, which is a characteristic feature of systems with configurational degrees of

freedom and, therefore, one key issue of relaxation theory. The most common explanation has been given by Adam and Gibbs [46]. Originally, it had been developed to explain structural relaxation but has since been generally applied to all relaxation phenomena including the underlying mechanism of viscous flow [47]. Thus, it has been possible to find a theoretical derivation of the widely used empirical (and essentially non-Arrhenian) Vogel–Fulcher–Tamann law of viscosity [48]. The basic assumption of this derivation, however, is that $c_{p,\text{configurational}} = \text{constant}/T$ holds, which is incompatible with the theory presented here. So the applicability of the latter is limited to a small temperature range, e.g. a small temperature range around the glass transition over which a constant value for $c_{p,\text{configurational}}$ and an Arrhenian temperature dependence of the relaxation times can be assumed.

The second issue is the assumption of thermorheologic simplicity that has been challenged by, e.g. Ducroux, Rekhson and Merat [49], who pointed out that thermal shrinkage effects and stress relaxation at temperatures much below the glass transition are poorly predicted by the linear thermo-viscoelastic theory as presented here. Their idea was to replace the constant Kohlrausch parameter b with a temperature-dependent one, i.e. $b(T)$, which takes the value “1” at some temperature between the glass transition and the melting point and decreases with decreasing temperature. Below the glass transition temperature, $b(T)$ will take so low values that the corresponding Kohlrausch function will comprehend comparatively fast relaxation processes, which in return will explain low-temperature relaxation effects. Again, these findings indicate that the applicability of the linear thermo-viscoelastic model as presented here is limited.

The third issue refers to fictive temperature and fictive pressure. An extension of Eq. (66) to the non-isothermal case has to take into account the equivalence of the effects of different parameters. Both a decrease of the fictive temperature and an increase of the fictive pressure lead to a density increase and, in turn, an increase of the relaxation time. This issue is addressed by current research (“density temperature scaling” [50]).

Reviewing the above three points, one comes to the conclusion that there is a definite need, both in glass science and glass industry, for a comprehensive and consistent relaxation model, which allows for all features mentioned.

Hyperquenched Glasses: Relaxation and Properties

Yuanzheng Yue

Department of Chemistry and Bioscience, Aalborg University, Aalborg, Denmark

1 Introduction

Besides melt-quenching, various different routes may be applied to obtain a glass [1]. For instance, vitreous silica can be prepared via vapor condensation, sol–gel techniques, and argon plasma or heavy-particle bombardment of crystalline silica. The most common route remains melt-quenching, however, which is why much work has been done on melt-quenched glasses to understand the glass transition and relaxation, along with their impact on glass properties (Chapter 3.7). Various experimental and theoretical approaches have been used for this purpose. One of the most effective is hyperquenching-annealing-calorimetric (HAC) scanning whereby a glass-forming liquid is first hyperquenched at a rate higher than 10^5 K/s, subsequently annealed below T_g , and then scanned by differential scanning calorimetry (DSC) [2].

Upon hyperquenching, the liquid structure is arrested in a highly “excited” configurational state owing to the extreme slowing down of the relaxation process with a sudden drop of temperature. Through sudden energetic and structural trapping at high temperatures, a liquid becomes a hyperquenched (HQ) glass far from equilibrium, which has a significantly higher fictive temperature (T_f) than a slowly cooled bulk glass. The energy evolution in the HQ glass during the sub- T_g annealing can be followed and quantified through a DSC upscan. Upon sub- T_g annealing and DSC upscanning, the highly excited configurational state is gradually relaxing so that T_f decreases. This feature makes it possible to observe the energetic development of a HQ glass well below T_g from

which information is gained about the structural heterogeneity of the corresponding liquid at $T = T_f$. From enthalpy relaxation, one can then infer how the potential energy and structure of the glass evolve upon annealing or dynamic heating and how both depend on the chemical composition of the material. In addition, the atomic vibrational dynamics in HQ glasses upon annealing can be observed with neutron, inelastic X-ray, or nuclear inelastic scattering techniques.

The present chapter reviews advances made in understanding relaxation of HQ glasses. The methods for determining T_f and cooling rate are presented. The relaxation features are correlated with the energetic and structural heterogeneities in glass. Striking differences in relaxation modes between strong and fragile HQ glasses are shown and discussed. As an effective method, the HAC approach is used to identify the so-called Johari–Goldstein relaxation and to reveal the thermodynamic change accompanied by the fragile-to-strong liquid transition. The potential-energy dependence of the vibrational properties of HQ glasses is illustrated. Finally, some perspectives in this research are briefly described.

2 Fictive Temperature and Cooling Rates

The fictive temperature (T_f) of a glass is the temperature at which the structure of its equilibrium liquid has been frozen-in (Chapter 3.7, [3–5]). It is determined by the cooling rate and the pressure applied to the liquid and represents the average level of the glass on the potential energy landscape. One of the reasons why it is important to quantify the thermal history of the glass in terms of both T_f and the cooling rate of glass is that these parameters exert a strong impact on mechanical and optical properties so that they are crucial for glass production

Reviewers: Joachim Deubener, Institute of Non-Metallic Materials, Clausthal University of Technology, Clausthal-Zellerfeld, Germany

process. The problem is indeed of great practical interest because it concerns in particular mineral and stone wool, which are very rapidly drawn and cooled down as fibers (Chapter 9.3), as well as metallic glasses produced as ribbons (Chapter 7.10).

In preamble, it must be stressed that the relaxation and physical properties substantially differ for HQ and slowly cooled glasses of the same chemical composition [6–8]. To picture the basics of enthalpy relaxation in HQ glasses, a stone-wool sample will be selected here. As produced with a cascade process (Chapter 9.3) and hyperquenching at a disc rotation speed of about 6000 rpm [2], the fibers have a mean diameter of about 3.5 μm and a standard T_g of 944 K (Figure 1). Their composition is (wt %) 41.5 SiO_2 , 21.3 Al_2O_3 , 1.6 TiO_2 , 7.3 Fe_2O_3 , 13.9 CaO , 11.7 MgO , 1.6 Na_2O , and 0.8 K_2O . In DSC upscans (Figure 1), there is a large difference between the measurements performed on the HQ sample (C_{p1}) and on the same sample reheated after cooling at 10 K/min (C_{p2}), which will be termed the *standard* glass sample [5]. In other words, the excess C_p of the HQ with respect to the standard glass originates in a potential energy gradually recovers upon dynamic heating, which of course depends on both glass composition and fictive temperature. Since the mechanical work done upon fiber stretching is small enough to be neglected, the excess enthalpy can itself be assumed to be the excess internal energy stored during hyperquenching.

To proceed further, it is useful to define T_c as the onset temperature ($=0.52 T_g$) of the enthalpy release, above which the fictive temperature gradually drops with increasing temperatures; T_e as the equilibrium temperature ($=1.06 T_g$) at which the quenched-in energy is completely released; T_s as the *shoulder* temperature ($=0.72 T_g$)

at which $C_{p1} = C_{p2}$ and the liquid returns to internal equilibrium; and T_{eq} as any temperature above the glass transition range [5]. The enthalpy (ΔH) released upon heating is then given by:

$$\Delta H = \int_{T_c}^{T_{eq}} (C_{p2} - C_{p1}) dT. \quad (1)$$

This excess enthalpy can alternatively be characterized by the fictive temperature T_f of the HQ glass. This parameter is determined with the enthalpy-matching method [5], which assumes that ΔH represents the excess enthalpy of the liquid with respect to the glass over the interval $T_g - T_f$ (Figure 2):

$$\int_{T_c}^{T_{eq}} (C_{p2} - C_{p1}) dT = \int_{T_{g,ref}}^{T_f} (C_{pl} - C_{pg}) dT, \quad (2)$$

where C_{pl} and C_{pg} are the isobaric liquid and glass heat capacities, respectively. For the HQ stone wool, one finds in this way a T_f of 1155 K ($=1.23 T_g$) if the C_{pg} curve is extrapolated to the liquid region with an equation of the form

$$C_{pg} = a + bT + c/T^2 + d/T^{0.5}, \quad (3)$$

where a , b , c , and d are constants.

If the viscosity–temperature relationship of the glass-forming liquid is known, one can in addition calculate the cooling rate q_c of the HQ glass with [5]:

$$\log q_c = 11.35 - \log \eta(T_f). \quad (4)$$

In Eq. (4), $\eta(T_f)$ is the viscosity at temperature T_f , which is 5.05 Pa.s, so that the cooling rate of the stone-wool fibers is about 2×10^6 K/s.

Figure 1 Excess enthalpy of a stone wool as given by the difference between the DSC of the HQ (C_{p1}) and standard (C_{p2}) samples at the same rate of 10 K/min. Inset: excess capacity, $\Delta C_p = C_{p2} - C_{p1}$, as a function of temperature (characteristic temperatures defined in text).

Figure 2 Determination of the fictive temperature T_f of the HQ stone wool with the energy-matching method. Same C_p data as in Figure 1, C_{pl} and C_{pg} being the liquid and glass heat capacities, respectively, and T_g the standard glass transition temperature.

3 Sub- T_g Relaxation

Determinations of excess enthalpies are just a first step in the characterization of HQ glasses as it is also important to know how enthalpy relaxes, i.e. to evaluate the rates at which the fictive temperature change and the excess enthalpy is released upon either static annealing or dynamic heating. Although enthalpy relaxation is a non-linear, non-exponential process, it has been extensively studied owing to its importance for understanding the nature of glass and the glass transition and for optimizing physical properties of glass products [4]. Most studies have dealt with slowly cooled glasses but scientists have recently realized that the enhanced nonequilibrium features of HQ glass fibers and ribbons make these materials particularly interesting for studying the glass transition and relaxation phenomena [2]. This is why sub- T_g annealing is a key approach to obtain dynamic and thermodynamic information on the glass transition.

Two parameters are independently acted upon in this respect, namely, the annealing temperature for a given time and the annealing time at a given temperature. Taking as a DSC reference the standard stone wool, one observes in the first case that, for HQ samples cooled at a rate of 2×10^6 K/s [2], the left cutoff of the enthalpy release peak (i.e. the exotherm below T_g) gradually shifts to higher temperatures until the peak completely disappears when the temperature T_a of eight-day annealing increases (Figure 3). Upon annealing, the configurational states of higher potential energy (or weaker bonding) are transformed into states of lower potential energy. When T_a is sufficiently high (but still lower than T_g), a pre-endotherm occurs below the onset temperature of the

Figure 3 Effect of the annealing temperature (T_a) on the enthalpy relaxation of stone-wool fibers annealed for eight days. Thick, dark curve: DSC upscan curve of the standard sample. Up- and downscan rates of 20 K/min.

exotherm (Figure 3). This pre-endotherm becomes larger with increasing T_a , but its onset remains constant. At the same time, the exotherm becomes smaller with T_a so that the exotherm and endotherm coexist in a certain range of T_a .

The annealing time t_a has a similar effect on the calorimetric response of the HQ stone wool at $T_a = 723$ K (Figure 4). When the annealed sample is heated from room temperature to T_e , a pre-endotherm again appears, followed by an exotherm [2]. The pre-endotherm becomes more pronounced with t_a and shifts to higher temperatures until the exotherm disappears. This feature implies that, upon sufficient annealing, the potential energy of weakly bonded structural units in the HQ glass drops to a level below that of the standard glass, and finally to that corresponding to the given T_a , whereas that of strongly bonded structural species remains higher than that of the standard glass.

Besides, a simple way to determine the relaxation kinetics is to consider the time dependence of the fraction $\Delta H_{\text{rem}}/\Delta H_{\text{tot}}$ of the excess enthalpy that has not been released during the DSC upscan (Figure 4, inset). One can then make a fit made to the experimental data with a Kohlrausch function $\Delta H_{\text{rem}}/\Delta H_{\text{tot}} = \exp[-(t/\tau)^\beta]$, where τ is the characteristic, temperature-dependent relaxation time, and $\beta \in (0, 1)$ is the stretching exponent describing the broadness of the relaxation time distribution (Chapter 3.7). The value $\beta = 0.16$ obtained for $T_a/T_g = 0.66$ is much lower than that those found in the energy-landscape influenced regime ($0.45 < T/T_g < 1$). The small

Figure 4 Effect of the annealing time (t_a) on the enthalpy relaxation of stone-wool fibers annealed at 723 K. Thick, dark curve: DSC upscan curve of the standard sample; up- and downscan rates of 20 K/min. Inset: $\Delta H_{\text{rem}}/\Delta H_{\text{tot}}$ as a function of t_a , where ΔH_{rem} is the enthalpy remaining in the sample after annealing and ΔH_{tot} is the total energy stored by HQ; solid line: Kohlrausch fit to the experimental data.

β value derived thus indicates that the distribution of relaxation times of the HQ glass upon annealing at 723 K becomes broader compared to that of the standard glass.

Additional information on energetic and structural heterogeneities in glass near T_g may be obtained through stepwise annealing studies [2]. Upon annealing, the relaxing parts of microstructures become less disordered and more stable in comparison with those of the standard glass. When the annealed HQ glass is upscanned in DSC, the degree of disorder in the relaxing part of the structure increases and gradually approaches that of the standard sample. This process leads to an endothermic event, i.e. to a pre-endotherm whose extent increases with both T_a and t_a . The pre-endotherm occurs only when the glass is hyperquenched and then annealed. It is more pronounced for glasses with higher T_f than for those with lower T_f under the same annealing conditions [2, 6].

Additional features of the pre-endotherm of the annealed stone-wool samples are noteworthy (Figure 5). The sample annealed for eight days at 773 K exhibits a pronounced pre-endotherm (Curve 1 of Figure 5), which completely disappears when the annealed sample is reheated in DSC to the crossover temperature ($T_{\text{cross}} = 897$ K), then cooled down to room temperature, and finally reheated to the maximum temperature (Curve 2 of Figure 5). At the same time, the exotherm remains unaffected.

The pre-endotherm of the annealed HQ glass and the T_g endotherm of the standard sample have different physical origins. One can eliminate the former and then

Figure 5 Isobaric heat capacity (C_p) as a function of temperature (T) showing the influence of heating condition on the pre-endotherm of the stone-wool sample subjected to a sufficient degree of the annealing. Curve 1: the sample annealed at 773 K for eight days; Curve 2: the sample annealed at 773 K for eight days, and then heated from 298 K to the crossover temperature (T_{cross}) of 897 K; Curve 3: the standard sample.

recover it by properly choosing heating and reannealing procedures. In contrast, the T_g endotherm is not removable by heating and annealing processes as it always occurs in up- and downscan as long as crystallization is avoided. The T_g endotherm is of course caused by the glass transition, which is accompanied by an abrupt increase in configurational entropy whereas the pre-endotherm is a signature of the strong non-exponential relaxation of the HQ glass upon annealing. As a matter of fact, all types of glasses have a spectrum of relaxation times, which implies the existence of many micro domains of different T_g values [2].

4 Anomalous Relaxation

The stone wool considered in previous sections is a relatively fragile liquid, whose viscosity–temperature relation is thus strongly non-Arrhenian (Chapter 4.1). Since relaxation is closely related to liquid fragility (Chapter 3.7), it is useful to turn now to germania (GeO_2), a strong liquid [9] whose HQ glass will be compared with that of calcium metaphosphate (CaP_2O_6), another fragile melt [10]. Even when plotting the DSC ΔC_p curves against the normalized temperatures T/T_g to account for T_g differences, there is a striking difference between both materials in terms of the T_a dependence of enthalpy relaxation. For HQ CaP_2O_6 (Figure 6a), the left cutoff of the ΔC_p peak gradually shifts to higher temperature with increasing T_a ($< T_g$) for $t_a = 12$ hours, whereas the right cutoff remains unmoved until the entire ΔC_p peak disappears. In contrast, for HQ GeO_2 (Figure 6b), the entire ΔC_p peak height becomes lower with increasing T_a ($< T_g$) for $t_a = 24$ hours. In other words, enthalpy release much differs in strong and fragile systems regarding the effects of the annealing temperature.

For HQ GeO_2 , annealing at a single temperature T_a below T_g (representing kinetic energy) can thus make complete relaxation of all structural units possible. In other words, the release of potential energy affects all network structural units and, hence, all sub-fictive temperatures (sub- T_f) characterizing distinct microstates with a kinetics that is determined by both T_a and t_a . Such a type of relaxation confirms that there exists only a single megabasin in the energy landscape of a strong system [11]. Similar relaxation phenomena are observed for HQ SiO_2 glass [11], indicating that the simultaneous and collective relaxation of all structural units is a universal feature for strong glass formers. In contrast (Figure 6a), relaxation in fragile systems proceeds in such a manner that some configurational states relax whereas others still remain unaffected, pointing to a great many well-separated megabasins in the potential energy landscape [11].

Figure 6 Effect of the annealing temperature (T_a) on the ΔC_p curves. (a) HQ CaP_2O_6 (fragile system) annealed at different T_a for the annealing time of $t_a = 3$ h; (b) HQ GeO_2 (strong system) annealed at different T_a for $t_a = 3$ hours. The DSC up- and downscan rates are 0.33 K/s. The T_g values of CaP_2O_6 and GeO_2 are 797 and 830 K, respectively. Dashed line: the standard sample.

Another pronounced difference in enthalpy relaxation between the fragile and strong systems is revealed by Figure 6a. In annealed HQ CaP_2O_6 , a pre-endotherm is observed before the exothermic peak occurs when T_a is sufficiently high but below T_g . Such a pre-endotherm is not observed for HQ GeO_2 , which is further evidence for less energetic and structural heterogeneities in strong systems compared with fragile ones. Because the effects of t_a and T_a on the enthalpy relaxation of both HQ CaP_2O_6 and GeO_2 are similar (Figure 7), the influence of t_a on the potential-energy landscape of the strong systems differs from that of fragile ones. These findings are not only of scientific interest, but also of potential technological importance. The optical and mechanical properties of glass fibers are strongly influenced by sub- T_g annealing. An improved knowledge of relaxation of HQ glasses may thus contribute to optimizing the forming and annealing processes of $\text{GeO}_2/\text{SiO}_2$ fibers with respect to these properties.

In the same spirit, many systems have been studied by means of the HAC approach to explore the effect of the

Figure 7 Effect of the annealing time t_a on the ΔC_p curve. (a) HQ CaP_2O_6 (fragile system) annealed at $T_a = 663$ K for different t_a ; (b) HQ GeO_2 (strong system) annealed at $T_a = 650$ K for different t_a . The DSC up- and downscan rates are 0.33 K/s. Dashed line: $\Delta C_p = 0$ for the standard sample.

liquid fragility on enthalpy relaxation in HQ glasses. It has been found that two main distributions of relaxation times determine the shape of the excess ΔC_p curves of the annealed HQ glasses. As reflected by high- T relaxation around T_g , one is associated with α relaxation, which accounts for global relaxation of the structural network. As embodied by relaxation well below T_g , the other is associated with β relaxation, which is likely related to local potential-energy lowering between network modifiers and non-bridging oxygens.

5 Modeling of Sub- T_g Relaxation

In glass relaxation studies, the Tool–Narayanaswamy–Moynihan (TNM) model (Chapter 3.7, [12]) is widely used since it describes reasonably well the calorimetric response to annealing temperature and time. Alone, however, it does not describe enthalpy relaxation in HQ glasses [13] or upon sub- T_g annealing. In this context, therefore, another promising approach is based on a new stretching function in the TNM model, which describes two well-separated distributions of relaxation

times and takes into account the substantial broadening of the glass transition region during the HQ process [14]. For fragile systems, this modified model predicts well the enthalpy response of both HQ and partially annealed HQ glasses under dynamic and isothermal heating although its physical foundations remain to be built firmly. In this respect, one should mention that a molecular dynamic simulation study has also succeeded in reproducing the annealing-induced pre-endotherm in HQ glassy water [13]. But there are still no suitable models for describing sub- T_g relaxation in strong glass formers such as HQ GeO_2 and SiO_2 . This is a challenging subject for future research.

6 Boson Peak

The vibrational dynamics exerts a determining influence on physical properties in both the solid and liquid states (Chapter 3.4). In this respect, an intriguing feature of the vibrational density of states $g(E)$ of amorphous substances is the existence of an excess of low-frequency states relative to the $g(E)/E^2$ values predicted by Debye theory. This excess manifests itself in incoherent inelastic neutron scattering or Raman spectra as the *boson peak*, between 2 and 10 meV, whose intensity depends on temperature, pressure, and chemical composition (Chapter 3.4, [6]). Although this energy interval clearly indicates that the peak is related to intermediate-range order, its structural origin remains debated in part because slowly cooled glasses have mostly been investigated. It is nonetheless agreed that distinct configurational excitations involve structures in which low-frequency modes, presumably with a transverse character, are generated.

Since they possess much higher potential energies and larger degrees of disorder, HQ glasses represent good systems to clarify the origin of the boson peak in terms of low-frequency modes involving large clusters, nanoparticles, mismatching or connected rings, or small tetrahedral rocking groups. In addition, HQ glasses have over liquids the advantage of sampling high-temperature structures that can be studied without any adverse effects from quasielastic scattering [6]. For this purpose, cold-neutron inelastic scattering with time-of-flight measurements is a particularly appropriate technique because its output, $Z(\omega)$, approximates the vibrational density of states if effects such as multiphonon and multiple scattering can be ignored.

Such experiments made for stone-wool fibers clearly show how the intensity of the boson peak decreases with decreasing T_f from HQ to superannealed glass before vanishing in the crystallized material [6]. The vibrational properties of a HQ and a well-annealed glass have been

Figure 8 Influence of structural disorder on the $Z(\omega)$ function regarded as an approximate representation of the vibrational density of states. Data shown up to 160 cm^{-1} for the stone wool in hyperquenched, standard-cooled, annealed, and crystalline states, respectively [6]. Annealed glass obtained by annealing of the HQ sample for 21 hours at 894 K ($0.94T_g$), crystallized sample by holding the glass at 1156 K for 150 minutes.

studied by nuclear inelastic scattering [15]. Although the former shows a higher number of vibrational states in the low-energy region than the latter, both vibrational densities of state become identical if they are renormalized after rescaling the energy axes in Debye energy units. This result indicates, on the one hand, that the decrease of Debye energy originates in density and sound velocity decreases and, on the other hand, that the effects of quenching and annealing on the boson peak may be described in terms of the transformation of a continuous medium. In particular, quenching does not affect the intensity of the boson peak, i.e. the relative excess of states above the Debye level so that the increase of the number of states is compensated by a corresponding increase of the Debye level. The higher heat capacity of glasses than crystals is not due to disorder, but to a lower density [16]. It is likely, therefore, that suppression of the boson peak upon more complete annealing (Figure 8) might simply be caused by an increase of the sample density.

7 Resolving Glass Problems Via Hyperquenching-Annealing Calorimetry

7.1 Johari–Goldstein (JG) Relaxation

Among different kinds of secondary (β) relaxations preceding the primary (α) process, a slow one was discovered on rigid molecules by Johari and Goldstein in 1970 [17].

This Johari–Goldstein (JG) relaxation plays an important role in the glass transition because it involves motion of all parts of a molecule. Even though much progress has been made in its study, the physical nature of this motion is still far from thoroughly understood. To the important question of whether the JG relaxation also occurs in strong glasses and in metallic glasses, one can answer by applying the HAC approach.

With this approach, it has been found that the strong HQ GeO_2 relaxes in such a manner that all secondary relaxation units contribute to the primary relaxation [11]. By analyzing the dynamic properties of the secondary (β) relaxation in the HQ GeO_2 glass, one identifies two typical features of JG relaxation. First, the quantitative relationship observed here between E_β , the activation energy of β relaxation, and T_g , $E_\beta = 23.5RT_g$, agrees well with the empirical expression of the JG relaxation, i.e. $E_\beta = 24 RT_g$ [18]. Second, the characteristic β relaxation time of GeO_2 glass at T_g is about 10 seconds, which is longer than that of relatively fragile systems. These results confirm that the JG peak in strong glasses is hidden in the α peak of the dielectric-loss curves. With the HAC approach, the dynamics of β relaxation in HQ metallic glasses like $\text{La}_{55}\text{Al}_{25}\text{Ni}_{20}$ ribbons in addition exhibits a typical feature of the genuine JG relaxation, since the variation of its activation energy (E_β) with T_g , namely, $E_\beta = 26.8 RT_g$, is also close to the aforementioned relation. In summary, JG relaxations are intrinsic features of both strong glass formers and metallic glass formers.

7.2 Mechanical Properties

In centrifugal fiber spinning, glasses are not only thermally hyperquenched, but also mechanically stretched with a degree of anisotropy that is frozen-in upon quenching and can be enhanced through increases of the axial stretching force. The anisotropy also depends on composition and, thus, on structure through the relative easiness with which the structural units align themselves with the fiber direction. As quantified by optical birefringence measurements, a higher anisotropy can thus be achieved with the same stretching force for glasses with one-dimensional (e.g. metaphosphate) than with three-dimensional (e.g. soda-lime-silicate) structural units. Enthalpy relaxation upon annealing or dynamic heating includes such a contribution from structural anisotropy. Compared with the slow mechanisms discussed above for the whole glass network, the difference is that anisotropy relaxation is fast because it involves only a more random arrangement of the local structure.

Regarding mechanical properties, the important point is that anisotropy relaxation causes the tensile strength of glass fibers to decrease, in agreement with the fact that fiber strength increases with the axial force applied [8]. In

other words, a larger drawing force yields thinner fibers, a higher quenching rate, and, hence, a higher T_f . In turn, a higher T_f is associated with a higher optical birefringence. Another noteworthy feature is that an increase of T_f has a negative impact on both the hardness (H) and elastic modulus (E) of glass fibers [7] as observed when these properties are successfully measured from indentation experiments made on single, thin glass fibers. The dependence of such mechanical properties on T_f can be studied for a wide range of HQ rates. Both H and E decrease linearly with a decrease of the fiber diameter (5–20 μm), i.e. with an increase of T_f . This trend may be readily understood in terms of an increase of the free volume with increasing T_f , which results in a lower resistance to indentation and deformation [7]. By varying the HQ rate and the degree of the sub- T_g annealing, one can in fact tune not only the mechanical, but also the optical properties of the glass.

7.3 Fragile-to-Strong Transitions

The fragility of a liquid represents the extent to which the temperature dependence of its viscosity and relaxation times depart from Arrhenian variations. The concept has in particular been widely used to characterize the dynamic properties of liquids in the vicinity of T_g . Based on this concept, liquids are normally classified as fragile and strong liquids (Chapter 4.1). An interesting observation made in this respect is that some glass-forming liquids do not conform to the conventional “strong/fragile” scheme, however, because their transport properties such as viscosity, self-diffusion constant, and relaxation time exhibit fragile-to-strong (F–S) transitions upon cooling [19]. Specifically, the viscosity of these liquids strongly deviates from Arrhenian laws around the liquidus (T_{liq}), but is close to Arrhenian near the glass transition range. These F–S transitions are a general feature of metallic glass-forming liquids so that an important question is to determine their structural origin. It is a challenge to answer it, however, because of very rapid incipient crystallization in the temperature and viscosity ranges where the transition takes place.

In spite of these difficulties, valuable information has been indirectly derived from HAC experiments. As illustrated by HQ $\text{Cu}_{46}\text{Zr}_{46}\text{Al}_8$ glass ribbons (Figure 9), a striking anomalous relaxation phenomenon is observed in the form of three-stage sub- T_g relaxation when T_a increases from 583 to 623 K, i.e. in the temperature range of the F–S transition. Likewise, changes in the two low- Q pre-peaks (P_1 and P_2) but not in the main peak (P_m) of the structure factor $S(Q)$ are observed with increasing T_a in X-ray scattering experiments (Figure 10). This constant P_m position indicates that the structural units that define short-range order (SRO) are stable. In contrast, the P_2

Figure 9 Effect of the temperature (T_a) of one-hour annealing on enthalpy relaxation as seen from the isobaric heat capacity (C_p) of HQ Cu₄₆Zr₄₆Al₈ glass ribbons [19]. Inset: relationship between T_a and the onset temperature of the exothermic peak (T_{onset}).

position slightly shifts toward higher Q values with increasing T_a , which could point to a monotonic decrease of intermediate-range ordering units. As for the position of P_1 , it varies in a zig-zag manner upon T_a increases, first shifting to lower Q values below 583 K, then to higher values from 593 to 613 K, and again to lower values above 623 K. Interestingly, this non-monotonic evolution is observed in the same T_a interval as that of the three-stage enthalpy relaxation (Figure 9, inset), which thus implies that the F–S transition of CuZrAl liquid is caused by a drastic transition in its medium-range order (MRO).

To go one step further, one can calculate the size of the structural unit involved in the process from Ehrenfest's formula $\ln \Omega_g = (h_m - h_c)/RT_g$, where Q_{pp} is the position of the P_1 pre-peak, and can thus determine its dependence upon T_a (Figure 10, inset). As expected, a marked negative anomaly is found between 600 and 620 K. It indicates a discontinuous evolution in MRO at the F–S transition, which cannot be accounted for by Adam–Gibbs theory of relaxation processes in which the size of cooperatively rearranging regions in the liquid is assumed to be a smooth function of temperature. Instead, the R_c decrease coinciding with the anomalous in enthalpy of the supercooled CuZr(Al) liquid upon cooling at around $1.3\text{--}1.4T_g$ has been attributed to dissociation of structural units into smaller clusters. Phenomenologically, the F–S transition would thus result from competition among MRO clusters composed of different locally ordered configurations [19].

7.4 Detection of Structural Heterogeneity in Glass

Structural and dynamic heterogeneities are universal in glass and are intimately connected to the glass transition relaxation phenomena. Dynamic heterogeneities in supercooled liquids, for instance, imply the existence of significant fluctuations upon quenching as a result of the reduction in the number of independent regions. Direct evidence for dynamic heterogeneities has been obtained from both calorimetric analysis and modeling of glass relaxation during sub- T_g annealing. Since

Figure 10 Non-monotonic evolution of the structure factor $S(Q)$ of HQ Cu₄₆Zr₄₆Al₈ glass ribbons with increasing annealing temperature (T_a) below T_g for one hour [19]. Bottom curve extracted from extended X-ray absorption fine structure (EXAFS) data. Shifts of the two pre-peaks indicated by dashed lines. Inset: structural unit size R_c of the first pre-peak (P_1) as a function of T_a .

dynamic heterogeneities are considered to have a structural origin, much effort has been made to clarify their mutual relationships.

In addition to structural properties, the potential energy in glass correlates with the dynamics at certain length scale since the mobility of an entity is higher when its potential energy is lower. Studies of enthalpy relaxation in HQ glasses have provided information on the energetic and structural heterogeneities in the supercooled liquids. With the HAC approach, it has, for instance, been established that the stepwise pattern of enthalpy release from HQ glasses with increasing T_a is due to structural heterogeneities [2]. The calorimetric signature of the structural heterogeneity has been obtained in HQ glass-wool fibers with the 20.8 CaO·15.6 MgO·62.2 SiO₂ composition (in wt %), hereafter abbreviated as HQ-CMS glass [20]. The fiber sample was attenuated from its parent melt at about 1873 K by means of a centrifugal cascade process. During the process, the fibers were hyperquenched at about 2×10^6 K/s. The HQ-CMS glass was subjected to a sub- T_g annealing protocol. The DSC results exhibit a striking phenomenon: two separated sub- T_g relaxation peaks in the HQ-CMS glass, implying the existence of two distinct structural domains of higher and lower potential energies, respectively. At the nano-scale, the higher energy domains are so unstable that they order even upon hyperquenching. This conclusion is verified by high-resolution transmission-electron microscopy images exhibiting nano-ordered domains in the glass matrix. The higher energy domains relax like a strong glass phase, whereas the lower energy domains do it like a fragile one.

8 Perspectives

The HAC approach is a sensitive and useful tool for studying the dynamics and thermodynamics of glasses and supercooled liquids that should benefit from technological and computing advances. Whereas new quenching technologies should make quenching rates faster than the current 10^{6-7} K/s possible, improved computing means should in contrast allow simulations to be made at rates slower than the current quenching rates (Chapter 2.9). A first promising outcome of such advances would be the possibility to probe the structure, potential energy, and dynamics of a liquid in the crystallization region of poorly vitrifiable systems, especially those showing fragile-to-strong transitions. A second positive outcome would be more extensive confrontations between experimental results and theoretical prediction of glass structure and dynamics. With the additional help of advanced microscopic characterization

techniques, these two aspects should allow structural heterogeneities in glasses to be explored quantitatively. In turn, key problems in glass sciences should be better addressed and receive new solutions. Cases in point are polyamorphic, liquid-liquid and fragile-to-strong liquid transitions, glass-formation, and structure-property relationships. Both applied glass science and technology are expected to be considerably advanced in this way.

Polyamorphism and Liquid–Liquid Phase Transitions

Paul F. McMillan¹ and Martin C. Wilding²

¹ Christopher Ingold Laboratory, Department of Chemistry, University College London, London, UK

² University of Manchester, Harwell, Didcot, UK

1 Introduction

Crystalline materials undergo first- and second-order phase transitions, leading to polymorphs having different structures and distinct physical properties. Similarly, different amorphous forms of glasses and other structurally disordered amorphous substances have been produced, depending on conditions of formation and processing. Polyamorphic transformations between different amorphous “phases” that appear to mimic crystalline phase transitions also occur as a function of variables such as pressure (P) or temperature (T). Because glasses and other amorphous materials are not in internal thermodynamic equilibrium, such analogies must be made with care, however. Thermodynamic transitions between non-crystalline phases can and do occur within the stable or supercooled liquid state, and these can be extrapolated below the glass transformation range in order to understand polyamorphic effects. Here we describe the topics of polyamorphism and density- or entropy-driven liquid–liquid phase transitions (LLPT) with examples drawn from systems that exhibit different phenomenological aspects. We begin with a discussion of LLPT that can occur as a function of pressure or temperature between liquid phases of the same substance that have distinct structures and thermodynamic properties.

2 Liquid–Liquid Phase Transitions and Polyamorphism

2.1 Density- and Entropy-Driven Phase Transitions in Solids

Thermodynamic transitions between crystalline phases are typically described according to Ehrenfest’s classification as of first or second order. In a first-order transition, two phases A and B have different free energies, $G(P, T)$, except at the equilibrium transition point (T_{tr}, P_{tr}) in temperature or pressure space where $G_A = G_B$, but discontinuities occur between the enthalpy (H), entropy (S), and volume (V) parameters of both phases. The $G(P, T)$ curves of both phases can be extended metastably into the pressure or temperature stability domain of the other, so a hysteresis results along with metastable coexistence of the two polymorphs. This is the type of transition envisaged in most discussions of polyamorphism and LLPT. The phenomena can also appear in relation to other pairs of coupled intensive/extensive thermodynamic variables. In a second-order transition, there is only a single common $G(P, T)$ relation for both phases that exhibits a break in slope at the transition point. Such second-order transformations have been suggested to interpret polyamorphism occurring in certain glasses and liquids, but the arguments are best considered after the concept of first-order LLPT has been introduced.

2.2 First-Order Phase Transitions in Liquids

The occurrence of first-order transitions between different liquid phases has long been known as a function of composition. Unmixing occurs when an initially homogeneous liquid separates into distinct phases in order to minimize the free energy, $G(X)$, where X is a compositional variable. However, the idea that chemically homogeneous liquids might experience first-order transitions between phases with distinct volume (density), entropy, and enthalpy parameters to minimize the free-energy function ($G(P, T)$) is less intuitively obvious. A typical view of liquid structure is based on a range of local structural environments engaged in rapid dynamic interchange and diffusional processes. However, the time-averaged and spatially averaged structures related to macroscopic thermodynamic properties such as H , S , V , and G are fully defined for the thermally equilibrated system. It is reasonable to envisage distinct liquid phases with a different range of local structural states and thermodynamic parameters, as atomic packing and bonding requirements respond to changing P and T conditions. The $G(P, T)$ curves for any two such liquids would then cross at a particular set of P_{tr} , T_{tr} values as the system seeks to minimize its free energy, resulting in a first-order LLPT.

The locus of P_{tr} , T_{tr} values plotted in P – T space terminates at a critical point (P_c , T_c). Thermodynamic analysis suggests that in most cases such a critical point exists below the melting line, so the phenomenon is typically observed only in the metastable supercooled liquid state.

The physics of density- and entropy-driven LLPT are well recognized for liquid helium in which quantum effects play a determining role. They are also used to describe liquid sulfur (covalently bonded chains and rings) and organic polymer systems where the balance of forces between covalently bonded chains with ionic head–tail groups results in liquid crystalline behavior. The general occurrence of density- or entropy-driven LLPT within liquids at constant chemical composition was predicted by E. Rapoport who extended the model of regular solution thermodynamics based on nonideal mixing of components with different partial molar volumes developed by E.A. Guggenheim to understand and interpret the unusual negative melting relations found among certain substances [1]. A similar approach was developed by L.I. Aptekar in order to explain the negative melting slopes of Si and Ge [2]. Aptekar's expression for the free energy of the liquids was derived from a general treatment of two level systems by S. Strässler and C. Kittel that considered the degeneracy of excitations above a ground state to predict and rationalize the order of a phase transition. This approach forms the basis for later “bond-excitation” models that have been used to describe the occurrence of an LLPT.

2.3 Melting Curve Maxima and Two-State Models

Most crystals exhibit a positive variation of the melting temperature T_m with pressure because the entropy change upon melting (ΔS_m) is positive as a result of the larger configurational entropy of the disordered liquid phase. Liquids also typically have a larger molar volume than isochemical crystals, so the melting volume ΔV_m is positive. The Clausius–Clapeyron relationship ($dT_m/dP = \Delta S_m/\Delta V_m$) then implies that T_m increases with pressure. Exceptions to this rule include the elements Si, Ge, Ga, Sb, Bi, Ti, and Pu and diverse compounds such as H_2O , InSb, and Li_2MoO_4 . In each case, however, the initially negative melting slope is followed by a normal dT_m/dP relation as a phase transition to a denser crystalline solid takes place. Maxima also occur in the melting relations for systems including the metallic elements Rb, Cs, Ba, and Eu; nonmetals such as I, S, Se, Te, P, Sb, and C; and compounds including PbTe, Bi_2Te_3 , KNO_3 , $NaClO_3$, Na_2SeO_4 , and KH_2AsO_4 . Explaining these anomalies required a new approach to understanding liquid-state structure and melting thermodynamics [3, 4].

Rapoport accounted for these unusual melting properties by observing that the density-driven phase transitions occurring below the melting line typically involve an increase in local coordination number or a change in the interatomic bonding. He thus proposed that the liquid contains a mixture of structural units from both types of crystalline phase whose relative proportions change continuously as pressure increases. Unlike in the crystal, the concentration of high-density units builds up continuously, so above a certain pressure the liquid density exceeds that of the underlying crystal and the $T_m(P)$ relation exhibits a maximum. If this maximum occurs under negative pressure, in a tensile regime, then an initially negative melting slope is observed as is the case for Si, Ge, and H_2O .

Rapoport treated these low- and high-density domains, or species, within the liquid as thermodynamic mixing components with partial molar volumes V_L and V_H , which could be estimated from the volumes of species contained within crystals or molecular cluster models. The relative proportion of each species is expressed as mole fractions (x_L , x_H) with $x_H = 1 - x_L$. Such “two-state” or “two-species” liquid models had already been considered previously, notably for H_2O where the liquid was suggested to contain a mixture of H-bonded and non-H-bonded regions with dynamic interchange between the two. In models of this type, it had generally been presumed that the mixing relations would be expressed by entropic contributions alone. Because of cooperative effects on the bonding overall along with interface energy contributions, however, Rapoport considered that an

energy (enthalpy) gain or penalty should arise from the simultaneous presence of the different structural species within the liquid state. With a simple regular solution model, the free energy of mixing for the two-state liquid then became

$$\begin{aligned}\Delta G_{\text{mix}} = & RT[x_L \ln x_L + (1 - x_L) \ln (1 - x_L)] \\ & + P[x_L V_L + (1 - x_L) V_H] \\ & + x_L(1 - x_L)W.\end{aligned}\quad (1)$$

Here R is the gas constant and T is the absolute temperature. The inclusion of the pressure-dependent term indicates that the relative proportions of low- and high-density species depend on compression, whereas the mixing parameter W denotes the magnitude and sign of the two-state contribution to the mixing enthalpy. The ΔG_{mix} function is minimized to obtain x_L at each P and T of interest and used to obtain the total liquid free energy $G_{\text{liq}}(P, T)$ for comparison with that of the crystal to calculate T_m as a function of pressure. Appropriate values of W are determined by comparison with experimental melting data. At high T a single minimum occurs, as expected for a homogeneous liquid phase, and the $T_m(P)$ relation develops a maximum as found experimentally. As the temperature is reduced, the ΔG_{mix} function develops two minima at different x_L as the temperature drops below a limiting value, indicating the onset of two-phase separation between LDL and HDL liquids containing different proportions of the low- and high-density species. The critical temperature at which the two minima appears is defined by

$$T_c = \frac{W}{2R}.\quad (2)$$

It varies as a function of pressure, resulting in a first-order phase transition line between the low- and high-density liquid phases of the same chemical substance. In his original paper, which sought mainly to develop a rationalization of melting curve maxima, Rapoport noted that “such separation into two liquids has, as yet, never been encountered and we therefore restrict ourselves to values of $W/kT < 2$ ” [1] (k being Boltzmann’s constant, i.e. R divided by Avogadro’s number). In fact this is precisely the LLPT phenomenon that is becoming recognized and discussed for a very wide range of liquid systems [3, 4].

Because the maximum mixing enthalpy $W/4$ is typically smaller than the melting enthalpy, ΔH_m , the LLPT generally lies below the melting line, in the supercooled liquid regime. Studies of LLPT are then experimentally difficult because the phenomenon finds itself in competition with stable and metastable crystallization, including precipitation of nanocrystals alongside the nucleation

events for LDL during cooling from the HDL phase. A notable exception to this behavior concerns the LLPT recorded for elemental phosphorus above the melting line under simultaneous high pressures and temperatures [5]. However, even this apparently non-controversial result raises new questions that are difficult to answer. The lower-density polymorph appears to be in a fluid, rather than a liquid, state: i.e. it lies beyond the liquid–gas coexistence line for the low-density molecular LDL phase. That observation then raises important thermodynamic points for future investigation concerning the topology of liquid–gas–fluid phase relations in systems containing a density- or entropy-driven LLPT.

The slope of the LDL–HDL transition is determined by a Clausius–Clapeyron relation. As $\Delta V_{\text{LDL–HDL}}$ must be negative, the main parameter is the entropy contrast between the low- and high-density liquid phases, containing both configurational and vibrational entropy components. Arguments can be advanced to suggest that the LDL–HDL transition might also generally have a negative dT_{LLPT}/dP slope [6], which appears to agree with observations for systems including H_2O , Si, Ge, and phosphorus, although it may not hold universally. The LLPT line then terminates at a critical temperature and pressure (T_c, P_c) determined by the respective enthalpy, entropy, and molar volume parameters of the liquid species, as well as by the strength of the mixing parameter W .

2.4 Relationship Between Liquid-Liquid Phase Transitions and Polyamorphism

In systems shown or suggested to exhibit an LLPT, the line of first-order phase transitions along with their associated spinodal curves can be extrapolated below the glass transformation range, so density- or entropy-driven LDA–HDA polyamorphic transformations mapping on to the LLPT are expected to occur (Figure 1). Substantial kinetic effects could also be present, including hysteresis resulting from overdriving the LDA–HDA transition as well as structural relaxation within both polyamorphs; such studies can help map out the location of the first-order LLPT and its spinodal bounds. However, polyamorphic phenomena can also be observed in certain systems that are not directly correlated with an LLPT, but instead represent the relative population or relaxation of different parts of the configurational energy landscape (CEL) that are accessed through different synthesis or processing pathways [7].

The two-state approach first investigated by Rapoport has now been made more general by incorporation of ideas derived from CEL interpretations of liquid properties [4]. In a version of the two-state model developed by Angell and Moynihan, liquids are viewed as being thermally “excited” from an ideal low-entropy ground state

Figure 1 Schematic relationships between melting curve maxima, liquid-liquid phase transitions, and polyamorphism phenomena.

that would correspond to that of a hypothetical ideal glass. Upon heating bonds become broken, new structural environments appear, and the configurational entropy (S_{conf}) increases. Within such a “bond-excitation” model, S_{conf} vanishes when the fraction of excited or broken bonds is reduced to zero in an ideal ground state. For a fragile liquid the configurational entropy should vanish at a temperature below the usual glass transition observed experimentally, consistent with the existence of a Kauzmann temperature (T_K) at which the excess configurational entropy of a crystal vs. glass would disappear.

If the model is extended to include enthalpic contributions because bond-breaking processes affect the excess free energy in the system, then a nonideal mixing energy parameter (W) arises. If W is sufficiently large, then the entropy reduction and the resulting appearance of the ideal glassy form should take place via a first-order polyamorphic transition. A slightly different form of the two-state model has been championed by Tanaka. Here the liquid is assumed to comprise two competing effects: a “normal” one in which crystallization is driven by density-induced ordering and another in which the energetics are determined by locally favored structures. In this model the “strong” nature of substances such as silica is explained in terms of increasingly large fractions of locally favored structures as the liquids are cooled and vitrify. Then LLPT and polyamorphism effects result if mixing of the normal and locally favored fractions is treated as thermodynamically nonideal with a sufficiently large value of W . Both models envisage an approach to an ideal, low-entropy amorphous state and can be applied to all supercooled liquid systems irrespective of whether or not they are prone to polyamorphism.

Interesting questions are raised by the fact that different glass transition temperatures (T_g^L , T_g^H) link LDL and HDL phases to their corresponding LDA and HDA equivalents (Figure 1). During supercooling the LLPT from the HDL phase can be encountered at a lower temperature than T_g^L , resulting in direct production of the low-density LDA glassy polyamorph from the high-density liquid phase. Likewise, heating an HDA polyamorph metastably quenched from the liquid state by bypassing the LLPT would cause transformation into the LDA state during reheating to above T_g^H . Such complex situations require careful interpretation of the structural and thermodynamic observations associated with the various polyamorphic and liquid-glass transformation events.

It is interesting to note that extension of the melting line into the supercooled regime and beyond, below the glass transformation range, leads to prediction of a metastable “melting” event, involving a direct transformation of a crystal into an amorphous solid during compression. This phenomenon termed “pressure-induced amorphization” (PIA) was first predicted and observed for H_2O (ice Ih phase), where it led to identification of a polyamorphic transition between HDA and LDA forms of amorphous ice [8, 9]. Because PIA occurs in a wide range of systems, it now constitutes an important area of materials physics investigation along with LLPT and polyamorphism ([2, 10], Chapter 3.10).

2.5 Observations of Polyamorphism in Glasses and Amorphous Solids

Depending on synthesis procedure, the existence of different varieties of an amorphous substance is a well-known phenomenon in materials science [7]. For example, amorphous SiO_2 samples prepared from melts quenched at different rates, sol-gel synthesis, neutron irradiation, PIA of crystalline quartz, and thermal destabilization of metastable stishovite have different values of the density, refractive index, and other properties. These observations have been linked to the presence of different populations of various structural units within the glass. Crystalline SiO_2 exhibits several polymorphs with different linkage patterns between the tetrahedral SiO_4 units, whereas defects including broken bonds ($\equiv\text{Si}^+-\text{O}-\text{Si}\equiv$), SiO_5 species (i.e. five-coordinated Si), and high-energy three-membered siloxane rings can appear within the amorphous state. Identifying the nature of the primary linkage patterns and the presence of defects has thus formed a large part of the discussion concerning the structure of vitreous SiO_2 as well as other well-known glasses.

Lebedev proposed that changes in the structure and properties of glasses during annealing might be

understood as analogs to the phase transitions that occur between crystalline polymorphs (e.g. among different forms of silica) [11]. That suggestion was made against the background of discussions concerning the fundamental structure of glassy materials, including “continuous random network” versus “quasicrystalline” models. Studying amorphous solids produced from crystals exposed to intense radiation and particle beams, Kreidl and co-workers introduced the concept of “amorphous polymorphs” to differentiate them from normal SiO_2 glass quenched from the liquid. In a footnote to an article describing the glass-forming ability of aqueous electrolytes, Angell and Sore discussed the possible existence and identification of distinct “vitreous polymorphs” for an amorphous substance. The concept of polymorphism in glasses was described theoretically by Landau and Nikolaeva, and the term “polyamorphism” was coined to describe the existence of different amorphous states with characteristic physical properties, by analogy with crystalline polymorphism [12]. The term was reintroduced by G. Wolf et al. to describe distinct structures adopted by vitreous GeO_2 as a function of the pressure [13]. Previously, the concept of glassy polymorphism had also been invoked to describe and interpret changes in the mechanical properties of SiO_2 glass during annealing and as a function of pressure cycling.

2.6 High-Pressure Studies of Glass

The effects of pressure on glass properties and structure have been investigated since the pioneering studies carried out by Bridgman and Simon. Up to approximately 10 kbar (1 GPa), most glasses show a typical elastic response similar to that demonstrated by crystalline solids. As the pressure is increased into the 5–10 GPa range, however, “permanent” densification is observed in glasses recovered to ambient conditions, accompanied by changes in physical properties and structure revealed by diffraction and spectroscopy studies, as well as by computational modeling.

As followed *in situ* during densification studies or thermal treatment, the observed changes in structural parameters or physical properties can occur over quite narrow pressure or temperature intervals and be associated with hystereses that depend on the timescale of the experiment. In some cases, the structural changes recorded can be reminiscent of those of the crystalline phase transitions that occur in similar P , T ranges. These observations then raise important questions about the fundamental nature of the polyamorphic event being studied. Is it mainly a more or less gradual change occurring within a macroscopically homogeneous amorphous “phase”? Or does it instead represent an amorphous analog of a crystalline or LLPT, with metastable coexistence

of distinct components, each having its own stability domain within the P , T space and being potentially separable macroscopically? Evidence for both types of interpretations is found among different classes of amorphous substance and even for the same substance studied under different conditions.

Glasses typically contain a range of structural units, including species and local coordination states, which are not found among crystals. Changes in glass structure and properties can occur more or less gradually as pressure and temperature are varied and can be reinforced by continued cycling. Such polyamorphism can be understood as continuous changes in the glass structure occurring as different aspects of an overall configurational energy surface are accessed through either different synthesis and processing approaches or different P , T annealing conditions within the internally non-equilibrated solid. However, polyamorphic transformations can also exhibit characteristics that suggest the presence of an underlying thermodynamic phase transition. They can also be accompanied by the development of interfaces between different amorphous forms, which can even be physically separated in certain cases. These phenomena can generally be correlated with an LLPT occurring (or expected to occur) within the stable or supercooled liquid equilibrium state. They imply the presence of an enthalpic barrier within the CEL separating different “basins” that correspond to the two liquid phases [3, 4, 10]. It is thus important to develop an understanding of the CEL interpretation of glassy and liquid structures.

2.7 Configurational Energy Landscape Interpretations

For a system of bound or interacting particles, the CEL is a multidimensional representation of the energy (free, enthalpic, or potential) determined by all possible relative arrangements of the particles. It is usually sketched as a “funnel” plot, where the energy is represented as a function of two selected interparticle coordinate dimensions or as a slice through the system following a pathway through the configurational coordinates (Figure 2).

Most configurations are highly unstable and constitute a high-energy background of multiple energy states. More stable configurations tend to define a “funnel,” leading to the lowest energy states of the system. Single configurations corresponding to crystalline atomic arrangements lead to sharp negative peaks in the energy surface: the most stable crystalline phase has the lowest free energy at a given set of P , T conditions, typically separated by high barriers from those of other crystalline phases that must be crossed via potentially multiple pathways as the P , T and other physical parameters are changed. The liquid phases of the system occupy a number of

Figure 2 Schematic depiction of a configurational energy landscape along a one-dimensional pathway through the multiconfigurational space defined by all possible interatomic and intercluster interactions in the system. At left is shown a relatively sparse range of configurations with energy minima separated by relatively high local barriers. Thermal population of a selection of these gives a low-entropy liquid or solid amorphous or glassy state if the energy is removed too rapidly to achieve a global energy minimum. The stable crystalline phase at the pressure of interest is denoted by a single deep, sharp minimum representing its single structurally ordered configuration. The “ideal glass” configuration might also be achieved as a material having no long-range crystalline order but minimal configurational energy resulting from a balance between long- and short-range ordering effects. At right appears a different set representing configurations that occur at higher interatomic density, expected to result in a larger number of minima separated by smaller barriers between them. These constitute a higher entropy solution to the amorphous solid. The two “megabasins” are expected to be separated by a high enthalpic barrier that can give rise to LLPT in the stable and supercooled liquid states.

energy minima that are equally filled under equilibrium conditions. The number of such minima that are accessed determines the configurational entropy (S_{conf}) to the liquid free energy. High-entropy liquids typically have a high density of configurational states that are readily accessed via low-energy barriers; they constitute the “fragile” liquids recognized by significant deviations of their viscosity from Arrhenian laws. Strong liquids have a lower density of configurational states available or high-energy barriers needed to access them. When thermal energy is removed, not all the minima are equivalently occupied, as the system becomes non-ergodic or “glassy.” Different interatomic configurations are preferred according to the T -quench rate, subsequent annealing conditions, or other glass synthesis and post-synthesis processing parameters. This picture can provide an interpretation of glassy “polyamorphism” as different local atomic configurations contribute in different ways to the overall structural state.

Upon compression, bringing the atoms closer together induces changes in the CEL topology that are determined by the relevant interatomic potentials. Crystal–crystal phase transitions are then made possible when the relative energetics of the different crystalline minima vary. In first-order transitions substantial free-energy barriers between the two phases persist, and the transformation pathways from one to the other phase involve multiple configurational components. Second-order phase transitions

proceed via uniquely defined pathways in coordinate space, with energy barriers that vanish as the CEL becomes modified under the new set of thermodynamic P , T conditions. Given the wider range of closely separated configurational minima, such second-order transformations could potentially occur in amorphous substances, but they must typically lose the sharp structural and thermodynamic definition among transformation pathways achieved among crystals. To date, no amorphous–amorphous transformations have been clearly identified as corresponding to phase transitions of a second-order character.

Within the CEL interpretation, different possible aspects of polyamorphism can be recognized. First of all, a different range of CEL minima will be occupied to a different degree depending on the mode of preparation of the glass or amorphous solid, resulting in a different spatially averaged structure and set of physical properties being recorded. In addition, different preparation methods such as PIA or irradiation of crystalline substances could result in CEL with different topologies. When temperature is increased, or as thermal annealing proceeds, internal structural relaxation takes place as the population of different minima tends to become more equilibrated. If pressure is applied, the CEL will change more or less rapidly, the minima associated with denser configurations appearing or becoming deeper and the pathways linking different configurational states becoming altered. The result could be a rapid, if not abrupt,

change in the concentration of certain structural features and physical properties, which could be described as “polyamorphism.” However, a polyamorphic transformation that might be mapped on to an LLPT should involve traversing an enthalpic barrier separating two regions within the CEL, each representing different amorphous basins containing multiple minima. The density of accessible minima at a given temperature represents the configurational entropy of each amorphous basin, and, as a function of pressure, one or another polyamorph will be energetically favored at low or high density (Figure 2).

3 Classic Systems Exhibiting Polyamorphism

3.1 H₂O: Thermodynamic Anomalies, PIA, and High- to Low-Density Polyamorphs

Liquid water is a remarkable substance with outstanding structural, physical, and thermodynamic properties relevant to materials, planetary, and biological science. It exhibits unusual effects such as a density maximum at 4 °C, a higher density for the liquids than for the crystalline ice Ih phase, and a melting relation with a negative slope between room pressure and 200 MPa. Crystalline ice contains H₂O molecules linked into a three-dimensional network by hydrogen bonding, resulting in an asymmetric, approximately tetrahedral geometry around each oxygen atom. Upon melting a fraction of the H bonds are broken and the structure collapses, resulting in the higher density of the liquid phase. A two-structured “flickering cluster” model for liquid water emerged in which H-bonded domains existed within a matrix of less associated H₂O molecules, the two undergoing dynamic exchange with each other.

Because of the rapid kinetics of proton exchange, solid amorphous H₂O can only be produced by extreme methods such as very rapid cooling rates from the liquid state. Amorphous solid H₂O was first prepared in what is now known as the low-density amorphous (LDA) form by the deposition of water vapor onto a cold substrate or by rapid cooling of micrometer-sized droplets of liquid water. In 1984, Mishima et al. carried out a key experiment to transform the crystalline phase directly into amorphous H₂O by compressing the solid at low temperature in order to intersect the metastable extension of the melting line [8]. This successful study revealed a textbook example of the phenomenon of “pressure-induced amorphization.” However, Mishima et al. noted that the amorphous H₂O produced existed in a previously unknown HDA form and that it could be transformed back into the LDA polyamorph by annealing at low pressure [9]. The transformation was abrupt, thus resembling a first-order crystalline phase transition. This feature has

become recognized as one of the classic manifestations of a polyamorphic transformation.

To investigate the anomalous properties of liquid water in its metastable supercooled state, Poole et al. devised a series of molecular dynamics (MD) simulations with a potential energy function that contained not only the primary energy minimum to model O–H covalent bonding but also a subsidiary minimum at longer distances to mimic the effects of hydrogen bonding. The results were remarkable. As thermodynamic properties were tracked to lower temperature within the supercooled state, emerging anomalies suggested the onset of a phase transition between different forms of water with high (HDL) and low (LDL) densities. These two liquid phases with different densities and entropies related to their structural arrangements could then be linked to the HDA and LDA forms and to the polyamorphic transformation observed between them in the non-ergodic solid amorphous state [14]. This work has stimulated efforts to observe and characterize the implied first-order LLPT that should take place within the supercooled liquid state of H₂O. Studies of bulk samples are hampered by rapid crystallization events that occur during supercooling from the liquid or heating of solid amorphous ices such that a “no man’s land” region has been designated in that region of the metastable phase diagram expected to link the two states of matter. Studies of water confined within nanoscale environments, along with experiments conducted at fast (picosecond) timescales, are now beginning to probe the structural nature and phase transformations of liquid water in this highly metastable regime. It must be noted that not all authors agree that an HDL–LDL LLPT actually occurs within the metastable phase diagram of supercooled liquid water, although recent simulations and experimental results point to its existence [14, 15]. Likewise, the complexity of polyamorphic transformations occurring within solid amorphous ice is being revealed by new experiments and simulation studies [4, 14, 15]. Neutron scattering experiments first suggested the occurrence of a “very high-density amorphous” (VHDA) state linked to the presence of a second polyamorphic transformation. Later studies indicate that this apparently new polyamorph could in fact be associated with a continuum of structural states existing as a function of annealing conditions. Linking metastable H₂O liquid behavior with the observed polyamorphism remains one of the great challenges of physical science [16, 17].

3.2 SiO₂, GeO₂, and BeF₂

Early work that led to development of the concept of polyamorphism arose from consideration of the structure of vitreous SiO₂. With its structure based on corner-linked SiO₄ units, this substance constitutes one of the main archetypal glass-forming systems. Crystalline varieties of

SiO₂ exhibit substantial polymorphism thanks to the different linkage patterns available, which vary as a function of the density. Different amorphous “polymorphs” are obtained by following different synthesis routes and annealing procedures. Different amorphous varieties are also produced by techniques ranging from sol–gel synthesis to intense particle or electromagnetic beam irradiation and PIA of crystals. These amorphous forms have distinct structural signatures and physical properties while maintaining an underlying structure based on tetrahedrally bonded framework motifs. Studies have recorded apparent transformations occurring between different silica “polymorphs” as the P , T or annealing conditions are varied. However, the structural and physical differences between the different amorphous forms more likely to correspond to gradual modifications within the same underlying CEL, rather than to completely different amorphous basins or landscapes accessed by surmounting an enthalpic barrier between different polyamorphic “phases.” As pressure is increased, the dense SiO₂ phase stishovite and other octahedrally bonded crystalline polymorphs become stabilized. This raises the prospect of glassy polyamorphism between tetrahedrally (SiO₄-based) and octahedrally bonded (SiO₆) structures.

The results and arguments for LDA–HDA, LDL–HDL, and related metastable transformations have been extended to other tetrahedrally bonded amorphous framework systems such as GeO₂ and BeF₂. In the case of GeO₂, there is clear evidence for density-driven polyamorphism associated with two-state behavior [13]. However, the existence of a critical point linked to a LLPT and pressure-induced polyamorphism in supercooled liquid SiO₂ at experimentally achievable temperatures is now being questioned from computer simulation studies [18]. Deciphering the occurrence and nature of polyamorphism phenomena in this classic series of glass-forming materials remains an active area of materials research.

3.3 Amorphous Semiconductors: Si and Ge

Like H₂O ice Ih, the elements Si and Ge both exhibit a negative $T_m(P)$ melting slope at low pressure. The diamond-structured semiconductor Si melts to form an electrically conducting liquid, which contains five- and six-coordinated structural species according to X-ray and neutron scattering experiments and MD simulations. Amorphous Si is a well-known semiconductor produced by vapor deposition techniques. It has a tetrahedrally bonded structure similar to the crystalline solid, but containing various broken bond or other structural defects. Rapid thermal analysis experiments suggested a metastable “melting” event located below the thermodynamic crystal–liquid transition temperature, by which the

LDA solid amorphous semiconductor transformed directly into the HDL metallic liquid. Recent fast time-scale experiments have clearly identified a glass transition linking the LDA with its supercooled LDL liquid. MD simulations and application of thermodynamic two-state liquid models indicate that an LDL–HDL LLPT event occurs in the metastable supercooled liquid regime [19, 20]. The critical (T_c , P_c) values are predicted to appear at slightly negative pressure, i.e. under tensile conditions of approximately –5 GPa.

Upon room-temperature compression of a porous variety of crystalline Si, Deb et al. observed PIA occurring above 14 GPa, resulting in an HDA form of a-Si. During decompression to ambient conditions, the structural signature of the normal LDA tetrahedrally bonded semiconductor reappeared. The results were analyzed in terms of PIA leading to the HDA polymorph above the upper spinodal line associated with the LLPT extended metastably below the glass transformation range, followed by back-transformation into the LDA form at the lower spinodal bound during decompression. The existence of an LDA–HDA transition was tested by pressurization studies of LDA a-Si combined with electrical conductivity measurements, as well as synchrotron X-ray and Raman scattering studies (Figure 3). The results mapped out an hysteresis for the polyamorphic transformation event consistent with theoretical modeling [20]. An analogous

Figure 3 Polyamorphism in a-Si upon compression and decompression. (a) Abrupt change in Raman spectra showing the transition from the tetrahedrally bonded LDA state to the metallic HDA polyamorph above 14 GPa. (b) Back-transformation from HDA to LDA below 8 GPa also visible in Raman spectra. (c) Mapping out of this reversible polyamorphic transition by electrical resistance measurements carried out in the diamond anvil cell. All pressures indicated in GPa.

Figure 3 (Continued)

high-pressure study of a-Ge by Barkalov et al. revealed superconductivity occurring in the HDA state, whereas Bhat et al. have quenched the high-pressure liquid to form a high-density metallic polyamorph.

The structural properties and relaxation dynamics within the high-*T* liquids have been probed by synchrotron X-ray scattering on levitated samples in a containerless regime and by MD simulations. The experiments revealed a gradual change in average Si coordination as the temperature was lowered, but no LLPT could be observed because of rapid crystallization in the supercooled regime. Likewise, MD simulations could not reveal directly the nucleation and growth of a second liquid phase, although anomalies developed in the thermodynamic properties indicated the approach to an LLPT.

Simulations carried out at temperatures approaching that of the LLPT revealed random volume variations occurring around the low- vs. high-density equilibrated states. These variations signal that the system is sampling HDL and LDL configurations within the CEL above the LLPT critical point. First-principles liquid state calculations show development of a sigmoidal shape in *P*–*V* isotherms indicating a transition between semiconducting (LDL) and metallic (HDL) forms. In the case of liquid Ge, Bhat and co-workers demonstrated that rapid quenching of a sample formed at high pressure in a diamond anvil cell resulted in formation of the HDA metallic polyamorph. These combined experimental, simulation, and thermodynamic modeling results clearly indicate the presence of LDA–HDA polyamorphism associated with an LLPT between LDL and HDL phases in the supercooled liquid regime for these technologically relevant systems. It is now of interest to explore and extend the manifestation of these polyamorphic events into binary Si–Ge and more complex systems based on elemental alloys within groups 13–15 of the periodic table.

3.4 Polyamorphic Transitions in the Y₂O₃–Al₂O₃ System

During studies of metastable crystallization and melting within the ceramic Al₂O₃–Y₂O₃ system, Aasland and McMillan first observed nucleation and growth of a second liquid occurring within the supercooled high-temperature liquid phase during quenching. Both liquids were arrested by the glass transition, so recovered samples contained coexisting glasses [21]. This phase separation was recorded for compositions ranging between 20 and 35 mol % Y₂O₃. In each case, the recovered glasses had experimentally indistinguishable chemical compositions, but their structures appeared to be different in microbeam Raman and FTIR spectroscopy experiments (Figure 4). In addition, backscattered electron imaging revealed a density difference between the LDA and HDA regions. The result was interpreted as a case in which the supercooled liquid system had traversed an LLPT line during cooling, which caused nucleation and partial growth of an LDL or LDA phase within the supercooled HDL matrix, resulting in coexisting LDA and HDA glasses following the quench.

Polarizable-ion molecular dynamics (PIMD) studies were carried out during supercooling of model liquids to understand the onset of polyamorphism. As *T* was lowered toward the expected onset of the LLPT critical behavior, the simulations showed random jumps between low- and high-density states, which equilibrated around larger vs. smaller volume configurations providing evidence for dynamic sampling of the high- and low-density basins within the CEL above the LLPT. Experimental

Figure 4 Evidence for polyamorphism in $\text{Y}_2\text{O}_3\text{--Al}_2\text{O}_3$ glasses. Optical microscope image of a polished sample obtained by quenching from a liquid with composition 20 mol % Y_2O_3 : 80 mol % Al_2O_3 (AY-20). During the quench segregated regions of LDA (top left) and HDA glassy material appeared with the same chemical composition. A clear interface between the two glasses is observed, and cooling cracks within the LDA phase do not extend beyond the boundary. The spherical shapes observed within the glassy regions represent gas bubbles and also LDA material exsolving within the HDL liquid matrix. The square outlines reveal the presence of YAG crystals formed simultaneously during the quench.

studies of supercooled $\text{Y}_2\text{O}_3\text{--Al}_2\text{O}_3$ liquids were carried out using containerless levitation combined with small- and wide-angle X-ray (SAXS, WAXS) and neutron scattering studies. Greaves et al. interpreted the SAXS results to indicate nanoscale density fluctuations prior to formation of the LDL liquid, in agreement with the PIMD results. Barnes et al. contested these results, suggesting that the samples contained nanocrystalline phases. Recent work has reconciled the contrasting results in terms of differences in sample composition and relaxation timescales.

3.5 The Case of Phosphorus: Liquid–Liquid vs. Liquid–Fluid Transitions

In X-ray scattering studies of liquid phosphorus under high- P , T conditions, Katayama et al. observed a first-order LLPT occurring in the stable liquid regime between 1050 and 2200 °C and $P = 0.3\text{--}0.9$ GPa [5]. The X-ray data indicated that the transition took place between an LDL phase containing discrete molecular P_4 units and an HDL polymeric liquid. Patterns taken at the transition point clearly showed a superposition of patterns of the two phases, and hysteresis occurred as P and T were varied. Further studies of stable and metastable phase relations in the phosphorus system show that the transition in fact occurs between the HDL polymeric liquid and the LDL

monomeric phase in a fluid state, i.e. beyond its liquid–gas equilibrium line. This situation highlights the fact that each liquid polyamorph must possess its own liquid–gas–fluid equilibrium relations. Likewise, each low- or high- density liquid polyamorph possesses a separate glass transformation (i.e. T_g^H vs. T_g^L , linking high- vs. low-density liquid [HDL, LDL] and solid amorphous [HDA, LDA] states) that must be taken into account when designing probe experiments and analyzing data to study polyamorphism and LLPT behavior.

3.6 Triphenyl Phosphite

Triphenyl phosphite ($\text{P}(\text{OC}_6\text{H}_5)_3$: TPP) forms a molecular crystal with $T_m \sim 295$ K. The supercooled liquid constitutes a “fragile” glass-forming system with distinctly non-Arrhenian relaxation properties, which can be studied down to its T_g of approximately 190–205 K. If the liquid is annealed between 210 and 223 K, however, a new, apparently amorphous, solid “glacial” phase nucleates and grows [22]. Initially this transition was thought to be between the supercooled liquid, which represented an HDL phase, and the glacial form, which represents the LDA polyamorph produced via an LLPT below the LDL glass transition. So much effort has been devoted in unraveling and understanding the nature of the glacial form of TPP and its metastable transformation that such studies became a central part of discussions concerning polyamorphism. It is now thought that the glacial phase likely represents a metastable nanocrystalline material with significant structural defects and disorder, although arguments based on LLPT and polyamorphism in the system continue to be discussed. Certain authors believe that the glacial form results from an LDL or LDA polyamorph that nucleates and grows within a matrix of the supercooled HDL phase via a first-order density- or entropy-driven LLPT. The nature of the polyamorphic transition in TPP is still under discussion.

3.7 Metallic Glasses

Amorphous metallic systems such as a-Fe are important technological materials, but they typically require very rapid quench rates ($>10^6\text{--}10^7$ K/s) to be produced from the liquid phase. However, complex materials containing various metallic and nonmetal components yield bulk glasses through cooling at rates of only $10^2\text{--}10^0$ K/s. This contrast can be understood partly in terms of the informal *confusion principle* according to which ease of vitrification improves within multicomponent systems with increased configurational entropy, covalent bonding, and lack of efficient crystallization pathways. These bulk metallic glasses are developed commercially for applications requiring

high mechanical resistance and specific electronic and magnetic properties. Early work on the high-pressure, high-temperature phase relations of metals such as Cs, Eu, and Ce revealed melting curve maxima interpreted by Rapoport using two-state structural models for the liquids and leading to the concept of LLPT and polyamorphism. Now density-driven polyamorphism has been discovered in metallic glasses such as $\text{Ce}_{55}\text{Al}_{45}$ linked to changes in the $\text{Ce } f$ orbital manifold with increased atomic packing [23]. During studies of Zr–Cu–Ni–Al–Nb–Ti supercooled liquids, abrupt changes between “fragile” and “strong” rheology noted in the vicinity of T_g could suggest the possible presence of an LLPT. Such metallic glasses and glass-forming liquids constitute a new family of systems in which polyamorphic or LLPT behavior could have technological consequences.

4 Perspectives

Polyamorphism, LLPT, and PIA are mutually linked phenomena forming an integral part of condensed matter physics and chemistry that is only just beginning to be appreciated and understood. They can occur generally among a wide variety of stable and supercooled liquids and condensed amorphous states exhibiting all types of chemical bonding. The occurrence of LLPT can be correlated with polyamorphism observed among glasses and other non-crystalline solids, but amorphous polymorphs can also be observed when different configurational states are accessed by different synthesis or processing pathways. There is also the possibility for multiple LLPT and polyamorphic transformations to occur within a given system as a function of the density. The existence of multiple liquid forms of a given substance induces rheological changes whereby viscosity and diffusion properties are related to the density and configurational entropy. These connections have implications not only for materials research but also for matter relevant to Earth and planetary sciences.

Quenching high- vs. low-density polyamorphs that may coexist metastably and growing metastable nanocrystalline phases within one or other of the polyamorphs raise the possibility of creating new nanocomposite materials such as ceramics, polymers, and metals with unusual and useful properties. Polyamorphism can lead to insulator–semiconductor–metal transitions between amorphous forms of the same substance. Polyamorphic phenomena can also be recognized among the collective excitations found in magnetic and dielectric materials. Polyamorphism concepts can be applied to the macromolecular chemistry of polymers and biomaterials where the CEL provides a useful common framework to understand folding and unfolding of proteins, polypeptides, and other

large-scale molecular systems incorporating covalent, ionic, and H bonding along with hydrophobic vs. hydrophilic interactions. We expect that useful applications of such analogies will grow with our understanding of polyamorphic phenomena and metastable phase transformations in general.

Pressure-Induced Amorphization

Paul F. McMillan,¹ Denis Machon² and Martin C. Wilding³¹ Department of Chemistry, University College London, London, UK² Institut Lumière Matière, Université Claude Bernard Lyon 1, Villeurbanne Cedex, France³ University of Manchester at Harwell, Didcot, UK

1 Introduction

Crystalline solids exhibit phase transformations between different structural polymorphs as a function of applied pressure, and they also undergo a melting transition into a liquid phase as temperature is increased. For most substances cooling the liquid rapidly allows the system to bypass crystallization, and a structurally disordered solid glassy form is obtained. Such glasses have many technologically important properties and applications that are well documented. However, certain classes of materials including liquid metals; elemental Si, Ge, and Se; and H₂O generally crystallize too rapidly for vitrification to occur. In these cases amorphization is achieved by other routes, including condensation from the vapor phase on to cold substrates, chemical synthesis reactions or rapid precipitation from solution, expulsion of solvent molecules from host–guest lattices resulting in collapse of the crystalline framework, and large-scale defect formation via bombardment of crystals by high-energy particle or radiation beams [1]. A further approach is to subject the crystal to high pressure at temperatures too low to enable the thermally activated processes of nucleation and growth of stable or metastable crystalline phases. The result then is mechanical destabilization to a structurally disordered material that can resemble amorphous solids produced by thermal quenching or other means. This process has been termed “pressure-induced amorphization,” or PIA, and it has now been reported to occur among many different classes of materials

[2–5]. Another aspect of PIA that is particularly relevant for Earth and planetary science applications is partial or complete amorphization of minerals during shock compression [5].

2 First Observation of PIA: Metastable Melting vs. Mechanical Destabilization of Ice Ih

The occurrence of PIA during static compression was first predicted and observed for the ice Ih polymorph of crystalline H₂O, which was compressed metastably beyond its normal stability range at low temperature (77 K) [6]. It was already known that ice had a negative dT_m/dP melting slope, which might be extended metastably below the normal melting line to below the proposed glass transformation range. That observation led Mishima and colleagues to predict that a “cold melting” event could occur through a quasi-first-order transformation between the metastably compressed crystal and a glassy phase at sufficiently low temperature (Figure 1).

During compression of ice Ih at 77 K, a rapid reduction in molar volume was observed at approximately 1.1 GPa, and the solid material recovered at ambient pressure was found amorphous upon X-ray examination. Mishima et al. concluded that PIA had occurred at a pressure that corresponded approximately to the predicted crossing of the free energy curves of the metastably compressed crystal and the solidified glassy state. That observation and its interpretation have resulted in the emergence of a new research field linking crystalline, glassy, and liquid state physics. The PIA phenomenon was subsequently reported to occur among a very wide range of substances with all types of chemical bonding [2–4].

Figure 1 Two schematic representations of pressure-induced amorphization. (a) A metastable melting event can occur as the crystalline phase (LP) with an initially negative $T_m(P)$ melting slope amorphizes at P_2 and low temperature instead of transforming at P_1 to a denser (HP) polymorph. (b) The metastable extension of the free energy $G(P)$ curve for the LP phase must terminate at some critical value. If the thermal energy is low, the system will become trapped in a locus of amorphous states (shaded gray), and PIA occurs instead of transformation to the HP phase. Likewise, decompression-induced amorphization may occur as an HP phase is recovered metastably to ambient pressure conditions (second shaded area above LP curve).

Attempts to understand the microscopic nature of the events leading to melting of crystals have occupied condensed matter scientists for well over a century. Thermodynamically, melting and the reverse process of crystallization from the liquid state occur at equilibrium as the $G(P, T)$ free energy relations for the two phases cross. However, because a first-order transition is associated with an enthalpic barrier, substantial superheating can occur if nucleation sites for melting are absent. Likewise, liquid samples can be supercooled well below T_m until the onset of the glass transition, resulting in formation of an amorphous solid. An atomistic model developed by Lindemann first considered that thermal excitation of vibrational modes resulting in critically large atomic or ionic displacements caused collapse of the crystalline lattice. Other interpretations have suggested that development of critical concentrations of “defects” including thermally induced vacancies, interstitials, or dislocations culminate in lattice collapse and in the onset of atomic, molecular, or ionic mobility, leading to a molten state. L. Brillouin and M. Born both considered the intrinsic limits of crystal stability in terms of mechanical constraints and in particular their need to maintain a resistance against shear stress. The elastic criteria presented by Born lead to a maximum upper stability limit determined for a given crystalline state, as a function of applied temperature or pressure [7].

All of these approaches have now been applied to understand the nature of PIA. Closely following the original observation of the effect and its interpretation as a metastable melting event, Tse and Klein [8] proposed that

amorphization of ice Ih arises as a result of shear instability within the crystal [8]. Further work revealed that the complex amorphization process could involve aspects of both dislocation- or defect-induced mechanisms as well as crystalline shear or even localized phonon instabilities. Understanding the PIA phenomenon has thus now become part of much wider discussions concerning the fundamental nature of stable and metastable transformations between crystalline, liquid, and amorphous solid states of matter.

A key aspect of all this work is identifying the amorphous nature of solids produced as crystals are pressurized beyond their stability limits at temperatures too low to initiate nucleation and growth of high-density crystalline phases. Various techniques are used to probe the structural state of samples and diagnose amorphization effects. However, they differ in their sensitivity to different length scales and degrees of structural order, which can affect the diagnosis of a PIA event [3, 4]. The observation of PIA also depends on the hydrostatic vs. non-hydrostatic nature of the compression conditions and the timescale on which they are applied, as well as the chemical purity, crystallinity and grain size of the starting samples. In certain cases, PIA reported initially from experiments carried out under less than hydrostatic conditions has been countered by careful compression studies of single crystals. Typically these results have led to identification of new crystalline phases formed via metastable transformation pathways in the superpressed solid [9, 10]. It has also become obvious that it is not always easy to distinguish between fully amorphous and

nanocrystalline or bulk crystalline materials containing a high density of defects.

Shortly following the initial observation of PIA in ice Ih [6], it was noted that the “glassy” material produced corresponded to a new high-density amorphous (HDA) form that could be recovered metastably to ambient conditions. That result sparked a further new field of research into the phenomenon of “polyamorphism,” which is linked to the presence of density- or entropy-driven liquid–liquid phase transformations (Chapter 3.9). Other observations showed that high-density crystals prepared at high pressure and recovered metastably to ambient conditions can also amorphize upon heating [5, 11] and that some high-pressure phases suffered catastrophic failure of the crystalline lattice caused by phonon instabilities during decompression [12]. However it is interpreted or achieved, PIA and related phenomena result in new families of structurally disordered solids that can have technologically important properties, including novel nanocomposites [4].

3 SiO_2 and AlPO_4 : “Memory Glass” Effects

Shortly after the report of PIA for ice Ih, R. Hemley et al. reported a similar effect occurring for the SiO_2 minerals α -quartz and coesite [13]. These phases are structurally related to ice polymorphs with Si–O–Si bridges between tetrahedral SiO_4 units taking the place of H-bonded H_2O frameworks. Using *in situ* X-ray diffraction in a diamond anvil cell, they showed that the crystalline materials transform into amorphous solids between 25 and 35 GPa at ambient temperature and developed a similar interpretation to that of Mishima et al. in terms of a metastable “melting” event. Although neither quartz nor coesite exhibit a negative melting relation, the authors proposed that a maximum appears in $T_m(P)$ for both phases in the 0–10 GPa region, consistent with incipient crossing of the metastably compressed crystalline and glassy free energies below T_g . Later work proposed alternative interpretations of the SiO_2 amorphization event in terms of a crystalline mechanical instability, similar to that suggested for H_2O ice Ih [14]. However, careful compression of single-crystal quartz under quasi-hydrostatic conditions results in transformation into a metastable crystalline (quartz II) phase rather than in PIA [9]. A detailed analysis of PIA occurring for the isostructural α -quartz phase of GeO_2 has been discussed in terms of collapse of the tetrahedrally bonded crystalline lattice [15].

It is important to recognize that PIA, along with all other metastable structural transformations occurring

during low-temperature compression or on a rapid timescale, is subject to kinetic effects that hinder bond-breaking and bond-reforming processes as well as atomic or ionic diffusion that would lead to an equilibrium ordered state. In addition, the distribution of applied stresses external to or developed within the sample is important, as deviations from truly isotropic or hydrostatic compression can provide lowered energy pathways or local driving forces, leading to PIA. Slower compression of single crystals under quasi-hydrostatic conditions results in metastable crystalline transformations, whereas compression of powders under non-hydrostatic conditions or on rapid timescales can lead to PIA of the same substance [9, 10]. The characteristic sensitivity to local vs. longer-range structural order of the probe technique used to investigate the phenomenon must also be taken into account in diagnosing PIA events [4].

In the example of berlinite (α - AlPO_4), which is isoelectronic with and structurally analogous to α -quartz, PIA was initially observed at around 13 GPa in a surprising way since the transformation appeared to be fully reversible, apparently conserving the orientation of the original crystalline axes. This unexpected result was described as a “memory glass” effect [16]. However, later work showed that the high-pressure “amorphized” form of AlPO_4 produced under the non-hydrostatic conditions of the original experiment was in fact a disordered crystalline solid [17]. Angle-dispersive X-ray diffraction experiments performed up to about 100 GPa have now demonstrated a two-stage densification process in which a hexagonal oxide sublattice forms first within the material, followed by redistribution of Al^{3+} and P^{5+} among the cation sites [18].

4 SnI_4 and Cu_2O : Examples of Compositionally Driven Instability

A crystalline-to-amorphous phase transition in SnI_4 under pressure was first described with laboratory X-ray diffraction and Raman scattering techniques [19]. The transition was initially thought to involve only the initial cubic crystal phase, but this interpretation was challenged by the observation of a second crystal phase at about 7.5 GPa. The pressure-amorphized SnI_4 phase emerged above 15 GPa and then crystallized at 61 GPa to produce a new structure with an fcc lattice containing I_2 units. This suggested that internal molecular dissociation could provide a driving mechanism for the metastable transformation phenomena. The latest work reveals a complex series of disordering and recrystallization transitions driven by electronic effects and atomic packing considerations [19].

Figure 2 Phase diagram of Cu oxides in stable and metastable regions. At ambient temperature, the cubic(I)-to-tetragonal(Ia) phase transition is observed in the Cu_2O stability region, whereas the two structural transitions Ia–II and II–III occur in the metastable region. The solid curves show the kinetic lines of the $\text{Cu}_2\text{O} \rightarrow \text{CuO} + \text{Cu}$ decomposition and $\text{CuO} + \text{Cu} \rightarrow \text{Cu}_2\text{O}$ synthesis, and the dashed line shows the equilibrium between Cu_2O and $\text{CuO} + \text{Cu}$ line. Source: Diagram redrawn from the original data of Ref. [20].

At ambient temperature semiconducting Cu_2O exhibits various structural and chemical transformations up to 20 GPa. In the equilibrium phase diagram of copper oxides, the equilibrium pressure of the reaction $\text{Cu}_2\text{O} \rightarrow \text{CuO} + \text{Cu}$ is 4–5 GPa at ambient temperature (Figure 2). Heating metastably compressed Cu_2O polymorphs at 30 GPa leads to the following sequence of events: (i) at around 410 K, Cu_2O becomes amorphous and remains so at least up to 535 K; (ii) further heating to 670 K yields a nanocrystalline two-phase mixture of $\text{Cu} + \text{CuO}$; and (iii) prolonged heating at this temperature leads to the full crystallization of this mixture. This sequence provides further evidence for amorphization driven by high-pressure decomposition reactions [20].

Other studies have proposed that PIA in complex solids results from kinetically hindered decomposition or disproportionation reactions of an initially chemically homogeneous crystalline phase. This model has been advanced to explain PIA observed among the family of LiMSO_4 compounds, where M is an alkali metal. The compound LiNaSO_4 does not undergo amorphization under pressure, whereas other members of this family do. One explains this result by noting that the combined volume of the decomposition products (Li_2SO_4 and M_2SO_4 , with $\text{M} \neq \text{Na}$) is smaller than that of the parent phase. However, more recent synchrotron X-ray diffraction studies have shown that LiKSO_4 in fact transforms to a high-pressure polymorph without any evidence for PIA, even under non-hydrostatic stress conditions [4].

5 Nanocrystalline Materials

At the nanoscale, materials exhibit physical and chemical properties that are different from those of the bulk crystals because of large surface/volume ratios. The thermodynamics and mechanical stress/strain relationships within nanoparticles are thus largely determined by surface free energy effects. The energetic contribution from electron quantum confinement also contrasts with a bulk band-structure description of the electron energy levels. The contribution of the surface energy can stabilize new polymorphs at ambient conditions and result in new properties. For example, the important semiconductor TiO_2 adopts a rutile structure in its bulk phase, whereas TiO_2 nanoparticles crystallize with the anatase structure; these nanoparticles are widely used for their photocatalytic properties. Another striking example of phase equilibria modified by surface effects is the melting process. The melting point depression observed for small particles has been known since the latter part of the nineteenth century and is described by the Gibbs–Thomson equation (i.e. J.J. Thomson, not W. Thomson, later Lord Kelvin) and derived in its modern form by F. Meissner and E. Rie. From a microscopic view, melting has been correlated to chemical disordering induced by point defects via a generalized adaptation of the Lindemann melting criterion. In nanoparticles, the surface considered as an extended defect is associated with a positive excess entropy, which is augmented further if the surface is defective. This leads to stabilization of the liquid or a solid amorphous phase below the glass transformation range, so both the kinetics and thermodynamics of melting or PIA are affected. Nanocrystals can also readily be prepared with few or no internal defects, and experiments show that they can be superpressed until the mechanically unstable elastic limit of the initial crystalline phase is reached. The resulting material is observed to be amorphous if there is insufficient thermal energy within the system to enable new crystalline structures to nucleate and grow.

In the case of the technologically important elemental semiconductor Si, PIA does not occur for the bulk crystalline material, but the phenomenon was observed for a porous nanocrystalline variety of p-doped π -Si compressed above 10 GPa at room temperature [21]. The onset of amorphization was recorded as a broadening and loss of the (111) nanocrystalline peak observed by energy-dispersive X-ray diffraction, whereas the Raman spectrum showed a fully amorphous broad signature by 12 GPa (Figure 3). Interestingly, the Raman spectrum did not correspond to that of a typical a-Si material based on tetrahedrally bonded units but instead resembled the vibrational density of states of a highly coordinated

Figure 3 Evidence for pressure-induced amorphization in nanoporous crystalline silicon. Left: Energy dispersive X-ray diffraction patterns showing initial sharpening of the principal (111) peak of the diamond structure followed by substantial broadening and finally disappearance of the crystalline diffraction above 10 GPa. Right: Raman spectra for porous Si at high pressure. During compression (a) the crystalline peak is replaced by the broad amorphous signal above 13–16 GPa from the HDA form of amorphous silicon. During decompression (b) the Raman spectrum for tetrahedrally bonded LDA a-Si emerges below approximately 5 GPa. Source: Data redrawn from [21].

metallic crystalline form such as Si-II (β -Sn structure). It was concluded that PIA had resulted in direct transformation into the HDA polymorph, which then back-transformed into the low-density amorphous (LDA) form of a-Si during decompression (Chapter 3.9). However, a more recent investigation of π -Si compression with Raman spectroscopy and angle-dispersive X-ray diffraction provides a slightly different view of the metastable transformation events [22]. The X-ray diffraction results indicate that metastably compressed π -Si transforms to the primitive hexagonal crystalline phase at about 20 GPa, which does not have a first-order Raman spectral signature. However, formation of the HDA form of a-Si was confirmed during decompression of the high-pressure phase, whereas the HDA–LDA transformation occurred at around 4.5 GPa, as observed initially. Recompression of the LDA state led to the transformation to the primitive hexagonal structure around 18 GPa. This reversible transformation proceeds via an HDA state.

The reversibility of the amorphous-to-crystal transition in nanomaterials under pressure has been discussed in terms of the nanocrystalline nature of the HP phase and an increase in Gibbs free energy associated with disorder at the grain boundaries [23]. Below a critical particle size, pressurized nanomaterials including TiO_2 , Y_2O_3 , and PbTe exhibit a crystal-to-amorphous transformation instead of their expected polymorphic crystalline phase transition. This observation highlights a greater propensity of

nanomaterials for amorphization that depends on the defect density and interfacial energy, which can be controlled by appropriate synthesis approaches.

6 Zeolites as Examples of “Perfect Glass” Formation

The idea of a “perfect glass” with a vanishingly low configurational entropy was first introduced by W. Kauzmann (Chapters 3.1 and 3.2). The arrest of atomic dynamics at the glass transition during cooling generally precludes formation of such a “perfect glass” state. However, structural collapse engineered by metastable compression of open-structured microporous materials such as zeolites provides an alternative route to prepare amorphous solids where thermally activated interdiffusion of ions or molecular species is not an issue. This approach to a “perfect” glassy state has indeed been followed through PIA of zeolites [24]. Typically zeolites consist of fully corner-connected $(\text{Al,Si})\text{O}_4$ tetrahedra, leaving cavities and channels of various sizes occupied in most cases by extra-framework charge-balancing cations or water molecules. The low-density microporous structures are already metastable with respect to dense crystalline polymorphs at ambient pressure, so volume collapse caused by compression at low temperature leads

to amorphization. A similar phenomenon is observed for H_2O –ice and semiconductor clathrate structures, as well as metal–organic framework (MOF) structures [25].

7 Configurational Energy Landscapes

As is the case for polyamorphism (Chapter 3.9), a convenient framework for interpreting the complex phenomenology surrounding PIA is provided by configurational energy landscape (CEL) models. These are constituted by a multidimensional plot of the potential energy (E) developed for all possible interparticle arrangements, defined by the bonding or other short- vs. long-range interactions between them. Each atomic arrangement constitutes a “configuration” that is typically represented schematically as a plot of energy vs. one or more of the generalized configurational coordinates. Between the deep, sharp minima representing ordered crystalline materials in the CEL occurs a “landscape” of amorphous configurations. As the pressure is varied, parts of the CEL change with respect to barrier heights. The relative positions of minima and pathways between these can be explored by thermal excitation, resulting in the variation of phase transition temperatures including melting, and the observation of metastable events such as PIA and polyamorphism. The CEL is affected by the extent of non-hydrostaticity of the field stress, including shear forces in different ways, and thus drives transformations that result in stabilization of new crystalline or amorphous polymorphs.

Two main scenarios are envisaged (Figure 4). In the first, the overall form of the CEL is assumed to remain

unchanged as the pressure increases, although the relative depth of potential minima and the barriers between them vary according to the relative density stabilization of different structural states. Pressurization at low temperature allows the crystal to be compressed metastably beyond its normal stability limit, until the $P\Delta V$ contribution to the energy allows the system to overcome local barriers and thus sample the surrounding configurational states. However, the thermal energy in the system is not sufficient to allow a suitable crystalline phase to nucleate and grow, so the resulting material is amorphous. In a second scenario, the topology of the CEL becomes modified during pressurization with the appearance, disappearance, or other modification of various minima and the barriers between them caused by mechanical, vibrational, or electronic instabilities, leading to collapse of the crystalline structure, but once more without permitting growth of a new crystalline phase.

Two critical factors govern the amorphization process: (i) the depth of the energy minima representing different crystalline states and (ii) the height of the energy barrier with respect to the amorphous megabasin, which can be increased by the number of defects (induced by doping, irradiation, etc.), surface/interface energy, strain, etc. Whenever this increase is sufficiently high, the initial crystal structure may be destabilized in favor of a new non-crystalline atomic configuration. Since the energy barrier between two crystalline phases that undergo reconstructive phase transformation is higher because of the need for bond-breaking and atomic diffusion events, amorphization may be easier to achieve under the low temperature and finite timescale conditions of the experiment.

Figure 4 Two scenarios for understanding pressure effects within a configurational energy landscape (CEL) model. (a) If the CEL is not modified by pressure, the crystal can transform either to the thermodynamic stable crystal C_2 or to a metastable amorphous state depending on the manner in which its potential energy is increased by an energy term $P\Delta V$. (b) If the form of the CEL varies with pressure, instabilities leading to collapse of the crystal structure toward an amorphous state may appear.

8 Perspectives

The occurrence of PIA has raised fundamental questions about metastability and phase relationships in systems compressed or decompressed at low temperature. As a system is perturbed from its initial equilibrium state, any transition between stable phases associated with processes that involve energetic barriers or species diffusion becomes kinetically hindered, and the system can find itself trapped in a locus of structurally disordered metastable states. If the system is initially in a nonequilibrium amorphous state, it can be induced to cross a barrier into another “basin” of amorphous states with different density through the application of pressure, resulting in pressure-induced polyamorphism. Sampling of deep crystalline minima may also occur simultaneously with the PIA or polyamorphism phenomena, leading to technologically useful strategies for formation of novel nanocomposite materials containing intimate mixtures of crystalline and amorphous regions or inclusions. Continued studies and development of an understanding of PIA, LLPT, and polyamorphism are thus set to improve our deeper appreciation of the transformation properties of condensed matter in a highly metastable regime.

Mechanical Properties of Inorganic Glasses

Russell J. Hand

Department of Materials Science and Engineering, University of Sheffield, Sheffield, UK

1 Introduction

Network glasses, such as silicates, are brittle materials in which network-forming species form strong and directional, covalent metal–oxygen bonds whereas network-modifying species form relatively strong ionic oxygen–metal bonds. Owing to these strong bonds, the structures of network glasses are difficult to rearrange under applied stresses so that these materials are stiff, hard, and brittle. The moduli of glasses depend on composition, being related to both the atomic bonding and packing present in the glass. In the case of metallic glasses, where bonding is metallic rather than covalent-ionic, atomic packing is the dominant factor in determining moduli rather than bond strength. Along with toughness, hardness, and brittleness, elastic moduli are material properties whereas strength is a specimen property that depends on sample preparation and history.

In considering glasses as brittle materials, it is assumed that the temperature of interest is sufficiently below T_g that purely elastic deformation can be considered. Thus, high stresses result in fracture rather than causing plastic deformation. The only exception to this is high enough stresses arising from contact that can result in local permanent deformation as well as in the formation of cracks.

To account for these features, the following topics will be dealt with in this chapter: the importance of flaws in determining the strength of highly brittle solids such as glasses; elastic moduli of glasses, which are of fundamental interest in that they are, at least in principle, calculable from interatomic potentials; hardness and contact damage; the need to use statistics

when dealing with the strengths of brittle materials such as glasses; stress corrosion and subcritical crack growth; and finally potential methods for overcoming or reducing the effects of flaws to increase the practical strength of glass.

2 The Importance of Flaws

As brittle materials, glasses are sensitive to the presence of flaws. The importance of flaws in controlling the strength of silicate glasses was first recognized by Griffith [1] (Chapter 10.11). The basic problem is that flaws that control the strength of glass objects are introduced not only during most commercial glass-production processes, but also during use by contact, whether with sharp objects (modeled by Vicker's indentation, see Figure 1a) or rounded ones (modeled by Hertzian indentation, see Figure 1b). The nature of the damage is also affected by the degree of packing in the glass. Under Vicker's indentation in “normal” glasses (e.g. soda-lime-silica), a permanently deformed diamond-shaped region is created, with radial cracks emanating from its corners, whereas in “anomalous” glasses, such as pure silica that have low packing densities, the cracking tends to be circumferential as observed under Hertzian indentation. The difficulty of atomic rearrangement means that the hardnesses of glasses, measured from the size of the permanently deformed region under indentation, tend to be relatively high.

The sensitivity to flaws means that the strength of any particular glass object may change with time as a result of damage induced during usage. In addition, a set of nominally identical glass objects will not have a single well-defined value of strength so that strength data need to be treated statistically, with usually either a normal or a Weibull distribution. Furthermore, although the fracture

of glass is usually perceived as sudden and catastrophic (brittle behavior), it was recognized as early as 1899 that loading of silicate glasses to failure at different loading rates gave different measured mean strengths. The reason is that subcritical crack growth can occur in stressed silicate glasses when atmospheric water is present, the rate of growth depending on humidity as shown by the classic data of Wiederhorn [2]. In recent times, water-induced subcritical crack growth has been a particular concern for predicting the lifetime of silica-fiber optic-telecommunication installations, although in reality, cable dig-up rate causes more failures than subcritical crack growth.

Coatings that fill flaws and are well bonded may be used to strengthen glasses (Chapter 8.2). Thick coatings are used to prevent damage in fiber optics whereas hot- and cold-end coatings on container glass are used during production to reduce frictional contacts and presumably to reduce contact damage. But a practical, transparent coating system providing both damage protection and strengthening by overcoming pre-existing flaws is currently not available.

A more widely used method of strengthening is to use compressive residual stresses, generated by thermal or chemical means and called thermally or chemically tempered glass, respectively (Chapter 3.12). The former is cheaper but is most effective with relatively simple geometries and requires reasonably thick glass. In comparison, chemical tempering is a much slower, more expensive process, but can achieve much greater levels of strengthening in a wider range of geometries including very thin glass, such as that used in mobile devices and modern display technologies.

Figure 2 Stress components acting on a small element of a body.

3 Moduli and Hardness

3.1 Stress, Strain, and Elastic Moduli

When a balanced force is applied to any material, stresses and strains (deformations) are necessarily produced. A given force can be resolved into three components each parallel to the principal coordinate directions. Considering the projection of these components onto a small area oriented perpendicular to a principal coordinate direction and dividing by the area then gives rise to one normal stress and two shear stresses (see Figure 2). Repeating this procedure for all three coordinate directions gives rise to nine components of stress. Thus, a full description of stress and strain at a point requires nine components of stress, σ_{ij} and similarly nine components of strain, ϵ_{ij} . On symmetry grounds, one can show that only six components of stress are independent, namely the three normal stresses and three of the shear stresses. Similar arguments can be used to show that there are six

independent components of strain. Stresses and strains are related via the moduli of the material in question, which are in turn ultimately linked to the atomic bonds in the material. In the most general case, six independent components of stress need to be related to six independent components of strain meaning that 36 independent moduli are potentially required to describe the relationship between stress and strain in a small region of material. However, as glasses are (usually) isotropic materials, only two independent moduli are required. These moduli can be any pair of Young's modulus (E), shear modulus (G_s), bulk modulus (B), and Poisson's ratio (ν). Once any pair has been obtained, the other moduli can be obtained via

$$E = 3B(1 + \nu), \quad (1)$$

$$G_s = \frac{E}{2(1 + \nu)}, \quad (2)$$

or related equations. The macroscopic moduli are related to stiffnesses and strengths of the underlying atomic bonds (two parameters that are usually proportional to each other and will thus be used interchangeably although they are not synonymous). As such, correlations between glass composition and the moduli of different glasses are expected and indeed are observed [3]. This relationship is not completely straightforward as atomic packing, which reflects the bond orientation, arrangement, and connectivity, also has an effect on the moduli of glasses; Poisson's ratio, for instance, essentially increases with packing fraction (see Figure 3), albeit in a nonlinear fashion, from pure silica to metallic glasses [3]. It is notable that many network glasses have similar packing densities, but different Poisson's ratios, hence Figure 3 shows a sharp increase in Poisson's ratio at a packing fraction of about 0.5. This indicates that varying bond strengths dominate the observed behavior in this region rather than the packing fraction, which is different from the monotonic trend predicted by the earlier model of Makashima and Mackenzie [4]. There is also a tendency for moduli to increase with the glass transition temperature, T_g (Figure 4; based on data from [5]), not because of a direct relationship, but because both moduli and T_g are related to the underlying bond strengths.

Typically, a small reduction in Young's modulus and shear modulus is seen as temperatures increase, a significant reduction being observed as the glass changes from an elastic solid as T_g is approached. Notably, pure silica, which is an anomalous glass, exhibits an increase in

Figure 3 Schematic plot showing the relationship between Poisson's ratio and packing fraction found by Rouxel (Source: Data from [3]) and the predictive model of Makashima and Mackenzie [4].

Young's modulus and shear modulus with increasing temperature.

3.2 Hardness and Plasticity

The difficulty of atomic rearrangement means that glasses tend to have high yield strengths and thus hardnesses, the hardness scaling with Young's modulus. Such high hardness values mean that, if subjected to indentation by a Vicker's diamond indenter, many glasses will be deformed in only a small volume. The presence of actual deformation does, however, demonstrate that glasses are *not* ideally brittle materials at room temperature. At sufficiently high temperatures, viscoelasticity will also occur with a concomitant reduction in measured hardness when T_g is being approached.

The nature of the deformed region under a room-temperature indentation changes quite markedly with atomic packing density. In this context, "normal" glasses, including soda-lime-silica, have a high packing density and show a diamond-shaped, permanent indentation, arising primarily from shear flow, with median-radial cracks emanating from its corners (Figure 5a). The median-radial cracks have been widely used to obtain comparative fracture toughness measurements (see, for example, [6, 7]), although the validity of this approach is now being widely questioned and may give contradictory trends when compared to more conventional procedures for measuring fracture toughness [8, 9].

"Anomalous" glasses, including pure silica, have low packing densities so that they much more readily experience densification under the indenter; for pure silica, 80% of the deformation actually arises from shear flow [10]. This gives rise to more circular crack patterns (compared to what is seen in "normal" glasses) around the indentation site with little or no radial cracking (see Figure 5b). The occurrence of both densification and shear flow in pure silica glass explains why pure silica glass has a lower hardness than its crystalline counterpart quartz, where only shear flow occurs under indentation. It is notable that the hardness of pure silica glass that has already been densified under high pressure significantly increases toward the crystalline values as deformation through shear flow becomes the only available mechanism [9].

Based on the dependence of the indentation stress field on Poisson's ratio, Rouxel and coworkers [8, 11] have recently categorized glasses as resilient ($0.10 \leq \nu \leq 0.20$), semi-resilient ($0.20 \leq \nu \leq 0.25$), easily damaged ($0.25 \leq \nu \leq 0.33$), or highly resilient ($0.33 < \nu$) reflecting how readily cracks can be generated around an indentation.

Recent work on ternary borate glasses [12] has demonstrated that in principle one may calculate hardness by considering the bonding constraints present in the glass. This constraint theory approach has previously been applied to chalcogenide glasses (Chapter 2.7). In some binary chalcogenide systems, a maximum in toughness and minimum in brittleness is observed around the rigidity threshold. Despite the correlations observed by Rouxel

Figure 5 Contrast between Vicker's indentations on "normal" and "anomalous" glasses. (a) Soda-lime-silica glass showing the centrally deformed region, cross-shaped median-radial cracks as well as primary subsurface lateral cracks, which are visible as interference fringes; (b) fused silica.

and coworkers [8, 11] or the work of Smedsjkaer et al. [12], however, the fact remains that there is no overall theory that predicts the variation of the mechanical properties of glass with composition.

4 Fracture Toughness and Strength

Arguments based on the energy required to break an individual bond can be used to show that the theoretical strength, σ_{th} , of any material should be a significant fraction of the Young's modulus of that material. The simplest version of these arguments assumes a sinusoidal approximation for the interatomic force–displacement curve and equates the area under the force–displacement curve with the surface energy, γ , of the new crack surfaces. This gives

$$\sigma_{th} = \sqrt{\frac{E\gamma}{a_0}}, \quad (3)$$

where a_0 is the interatomic distance. For soda-lime-silica ($E \approx 70$ GPa, $\gamma \approx 3.5$ J/m², and $a_0 \approx 0.3$ nm) Eq. (3) gives $\sigma_{th} = 29$ GPa $\approx \frac{E}{2.5}$. More complex models indicate that in general $\frac{E}{10} \leq \sigma_{th} \leq \frac{E}{5}$. In practice, however, the strengths of materials are usually significantly less than these theoretical values; in the case of bulk network glasses, practical strengths are of the order of $\frac{E}{1000}$. This is due to the presence of strength-controlling flaws or cracks, which are often referred to as Griffith flaws, although the precise nature of these flaws, and whether they have any relationship to the underlying glass structure [13] is still a matter for debate.

As glasses do not have a regular crystalline structure or grain structure, once a crack starts propagating, its

direction of growth is perpendicular to that of local principal tension rather than following microstructural features in the glass. Initially, this leads to distinctively smooth fracture surfaces that may be gently curved depending on the particular local stress field ahead of the growing crack (Figure 6). This type of fracture is referred to as *conchoidal*. Once a crack interacts with reflected stress waves, Wallner lines may be generated on the fracture surface. Alternatively, if the crack reaches its terminal velocity and starts to bifurcate, then features variously known as hackle or river lines may be generated (Figure 6).

Inspection of fracture surfaces shows that usually the strength-controlling defects are present in the original surface of the glass component. For a flaw of depth, a , oriented perpendicularly to an applied stress, σ_{app} , the ij th component of stress, σ_{ij} , at the crack tip is given by

$$\sigma_{ij} = \frac{C\sigma_{app}\sqrt{\pi a}}{\sqrt{2\pi r}} f_{ij}(\theta), \quad (4)$$

where r is the distance from the crack tip and f_{ij} is a function of θ , the angular distance from the line of the crack. The numerator of Eq. (4) may be written as

$$K_I = C\sigma_{app}\sqrt{\pi a}, \quad (5)$$

where K_I is known as the mode I stress-intensity factor. In general, C in Eqs. (4) and (5) is a function of crack length. For small surface cracks, such as those typically controlling the strength of glasses, it can be approximated as a short through-edge crack in which case $C \approx 1.12$. Although a through-edge crack is clearly a major simplification (see Figure 7) compared to real crack geometries, then this approximation gives reasonable insight for surface cracks in glasses if $a \ll W$.

Figure 6 The smooth curved surfaces associated with conchoidal fracture and river lines in an obsidian sample.

Figure 7 Schematic diagram of a through-edge crack.

Fracture occurs when

$$K_I \geq K_{Ic}, \quad (6)$$

where K_{Ic} is known as the critical stress-intensity factor which, in the absence of residual stresses, is equal to the fracture toughness, the measure of resistance to crack growth of a material. As a result, K_{Ic} is usually also referred to as the fracture toughness of the material. If residual stresses are present, however, it is better to differentiate between the critical stress intensity for fracture, which is related to the stresses present as well as the loading geometry, and the fracture toughness, which is a material property. Thus, in the following, K_{Ic} will be used for the critical stress-intensity factor for fracture and T for

the fracture toughness, i.e. if no residual stresses are present, then

$$K_I \geq K_{Ic} = T. \quad (7)$$

If residual stresses are present, then the condition for fracture, Eq. (7), becomes

$$K_I \geq K_{Ic} = T + K_{rs}, \quad (8)$$

where K_{rs} is the stress-intensity factor due to the residual stresses. For surface flaws restricted to the compressive stress region of thermally or chemically tempered glass, $K_{rs} > 0$, so that the critical stress-intensity factor at failure is greater than the intrinsic resistance to crack growth (in other cases, K_{rs} may be positive or negative). As a result, such glasses are sometimes, albeit incorrectly, referred to as toughened glasses; in practice, the underlying resistance to crack growth, i.e. the strength of the bonds in such glasses is essentially unchanged.

Glasses are often viewed as archetypal brittle materials because their fracture toughness is generally very low even in comparison with other brittle materials. Some typical values are given in Table 1. The ratio of hardness to fracture toughness, usually calculated from indentation approaches, has been labeled brittleness and suggested to scale with density for “normal” silicate glasses [14] although more recent studies have questioned this relationship [15].

The derivation of Eq. (4) assumes that cracks are infinitely sharp and that the stress becomes infinite at their tip ($r = 0$). In practice, this cannot be the case and some yielding will occur instead ahead of the crack tip. Owing to the difficulty of bond rearrangement in network glasses, which causes them to have very high yield

Table 1 Representative mechanical property ranges for different glass families.

Glass composition	E (GPa)	μ	$\frac{E}{1-\nu^2}$ (GPa)	Hardness (GPa)	Fracture toughness (MPa m ^{1/2})	Brittleness (μm ^{-1/2})
Soda-lime-silica	70–75	0.22–0.25	74–80	5.4–6.6	0.72–0.82	6.5–9
Silica	72	0.17	74	7.0–7.5	0.74–0.81	8.6–10

strengths, yielding occurs over a very small volume of material on the scale of a few interatomic distances at most. The very localized nature of such yielding means that this process does not significantly contribute to the resistance to fracture and, as a result, that the fracture toughness is very low. Hence the stress–strain curve of network glasses under tensile or bending loading is essentially linear until failure, which is usually sudden and catastrophic. As noted above, under compressive indentation loading, permanent deformation can occur.

5 Flaws and Strength

5.1 Flaw Sizes

The flaw sensitivity of glasses means that they are susceptible to damage by contact either with another glass component or with another materials; such contacts naturally arise during current production of most bulk glass. Other processes, such as the removal of the indented side regions (seldge removal) of a float glass ribbon, can also introduce damage and various distinct flaw types can be identified on the edges of float glass (Chapter 1.4). Once bulk glass is in use, post-manufacture, further contact damage can and does arise. Thus, the strength of bulk glass, even by the end of the production process, is much less than the theoretical value and will often be further reduced by damage occurring during use. Typical flaw sizes in as-manufactured glass are calculated with Eq. (5) and $C = 1.12$ to determine when the stress-intensity factor becomes equal to the fracture toughness, to be of the order of a few tens of microns in depth. In comparison, downdrawn silica-fiber optics are prepared with a fresh outer surface that is coated immediately after forming to protect the surface from subsequent contact damage (Chapter 6.4). In this case, flaw sizes are calculated to be on a nanometric scale. As a result, the strengths of such fibers are very high, especially if measured under liquid nitrogen or liquid helium so that stress corrosion (see Section 5) during testing is suppressed. The high strengths of silica-fiber optics are essentially maintained over time, thanks to the prevention of contact damage, although a limited degradation in strength called “zero stress aging” is observed, which arises from a roughening of the glass surface by water that diffuses through the protective coating.

As noted above, the typical size of surface flaws in bulk glasses is of the order of a few tens of micrometers. Although flaws of this size could, in principle, be visible prior to fracture, in practice they are generally not, suggesting that the strength-controlling surface defects in bulk glasses are tightly closed and thus not resolvable optically. Obviously, gross defects can be seen but,

depending on their position and loading geometry, these may or may not actually be the strength-controlling defect in a particular glass object.

Applying Eq. (5) to the strength of silica-fiber optics tested under liquid nitrogen gives a defect size similar to the size a SiO_4 tetrahedron. However, this value needs to be treated with caution in that the derivation of Eqs. (4) and (5) assumes that materials are continua, i.e. it ignores the existence of atomic-level structure despite the fact that the discontinuity of matter should be considered in describing phenomena at this scale. Given that the observed variation in the strength of these fibers can be accounted for by the variation in their diameter, the calculation does suggest that the strength-controlling features in silica-fiber optics are related to something intrinsic in the glass structure rather than to an externally imposed damage site. More generally, the strengths of glasses measured by testing of newly drawn fibers under liquid nitrogen, such that water attack is suppressed, have therefore been defined as intrinsic by Kurkjian et al. [16]. In this case, it has been found that the melt temperature and soak time before drawing affect the intrinsic strength [17], again suggesting that the strength-controlling features are related to features in the glass/melt structure such as alkali channels [13] although the actual cause of this effect is unclear. In most practical applications of bulk glass, however, strengths dominated by extrinsic flaws are the norm.

It should be noted that, even under ambient conditions, the strength of most glass fibers is significantly larger than that of the bulk glass of the same composition. This difference can be ascribed to the presence of smaller extrinsic defects in fibers than in bulk glasses, since large defects that can be present in bulk glass would simply result in a broken fiber, as well as possibly to the higher fictive temperature of fibers caused by the rapid cooling experienced during fiber production [17]. In addition, the degree of structural anisotropy caused by the drawing stress influences the measured fiber strength [18]. The presence of coatings that prevent or minimize surface damage thus enable these high fiber strengths to be maintained over time.

Although rapid cooling seems to aid fiber strength, the large gradients in temperature generated during cooling and, hence, of residual stress that would then be generated in bulk products would normally result in spontaneous fracture (unless carefully controlled to produce thermally tempered glass). Thus, bulk glass articles are annealed to avoid the formation of undesirable residual stresses that can cause spontaneous fracture. As cooling times essentially scale as the square of the section thickness, the annealing process for thicker sections is necessarily very long and expensive.

One particular area where cracking is potentially of concern is in vitrified nuclear waste. In a heat-generating wasteform, such as those produced by vitrification of high-level reprocessing wastes in the United Kingdom and France, significant self-heating from the intense radiation field probably mitigate, to some extent, against this cracking which has been directly observed on more rapidly cooled “inactive” simulant wasteforms. In addition, radiation damage will arise through radioactive decay. Although it is not clear what effect such damage will have on glass strength, it is probable that the size of these radiation-induced defects is insignificant compared to that of the cracks arising from temperature gradients on cooling. In practice, the vitrified nuclear wastes are contained in stainless-steel canisters, which provide mechanical integrity for handling so that cracking primarily affects the amount of surface potentially available for chemical attack.

5.2 Flaw Statistics

As the flaws generated by contact and other damage mechanisms are necessarily variable, the strengths of a set of nominally identical pieces of glass will also be variable and a statistical treatment will have to be applied to any glass strength data. The most commonly used treatments assume that the measured strengths follow either a normal or a Weibull distribution. The symmetric, normal distribution is characterized by two parameters, namely the mean, $\bar{\sigma}$, and the standard deviation, s , which can be readily evaluated with a scientific calculator or spreadsheet. Compared to the normal distribution, the Weibull distribution is arguably preferable in that it gives a greater emphasis to the low strength tail that is especially relevant from a practical standpoint. With limited datasets, however, there is unlikely to be sufficient evidence to favor either of these distributions over the other.

For the Weibull distribution, the basic analysis is a little more complicated and either two or three parameters may be used to characterize the distribution. The three-parameter Weibull distribution states that the risk of failure, F , is given by

$$F = 1 - \exp \left[- \left(\frac{\sigma - \sigma_u}{\sigma_0^*} \right)^m \right], \quad (9)$$

where σ_0^* is a characteristic strength (which, similarly to the mean in the normal distribution, is a measure of the position of the peak of the distribution); m is the Weibull modulus, which is a measure of the width of the distribution (with a large value of m indicating a narrow spread of strength values); and σ_u is the stress below which the probability of failure is zero. In practice,

because it is difficult to evaluate σ_u in a straightforward fashion, the two-parameter distribution

$$F = 1 - \exp \left[- \left(\frac{\sigma}{\sigma_0^*} \right)^m \right] \quad (10)$$

is often used instead of Eq. (9). The two-parameter distribution is intrinsically more conservative; however, its use may not be appropriate in all situations. Application of Eq. (10) instead of Eq. (9) is, for instance, particularly problematic when assessing the strengths of reinforcing fibers selected from a fiber tow [19]. In both Eqs. (9) and (10), the normalizing characteristic strength term is related to the loading geometry and the volume, V , or surface area, S , or for fibers length, L , of stressed material by $\sigma_0^* = \sigma_0 (L_f V)^{-1/m}$, $\sigma_0^* = \sigma_0 (L_f A)^{-1/m}$, or $\sigma_0^* = \sigma_0 (L_f L)^{-1/m}$, respectively, where L_f is a dimensionless geometry-dependent loading factor (1 for straight pull tension and a function of m for other geometries) and σ_0 is another normalizing term without obvious physical meaning due to its unusual dimensions (e.g. MPa m^{3/m} for the volume case). Use of the loading factors and σ_0 is only necessary if one tries to relate data from one sample geometry/size to another, a situation that will not be considered further here.

By taking logs twice, one can rearrange Eq. (10) into the form of a straight line

$$\ln [-\ln (1 - F)] = m \ln (\sigma) - m \ln (\sigma_0^*), \quad (11)$$

which provides a basis for evaluating the Weibull modulus. Thus, for a given set of data, one obtains the risk of failure, F , by ranking the strength values in ascending order and assigning each value a rank, r , duplicate values being assigned different adjacent ranks. The risk of failure may then be estimated with

Figure 8 Example of a Weibull plot, where σ is the measured strength and F is the estimated risk of failure. Source: Data from four-point edge strength measurements on float-glass samples.

$$F = \frac{r - 0.5}{N}, \quad (12)$$

where N is the total number of samples. Other similar estimators of F can be used instead of Eq. (12). A plot of $\ln[-\ln(1 - F)]$ versus $\ln(\sigma)$ ideally will yield a straight line the slope of which is the Weibull modulus and the intercept with the y -axis enables evaluation of σ_0^* . For the example Weibull plot shown in Figure 8, the Weibull modulus is 4.5 with an intercept value of -17.94 , hence $\sigma_0^* = 53.9$ MPa. Deviations from a straight line in the tails of the distribution (as seen in Figure 8) tend to reflect insufficient numbers of samples being tested; such deviations elsewhere in the plot may also suggest that more than one flaw type may be causing failure. One can rectify the former by increasing the numbers of samples tested whereas the presence of more than one flaw type requires more complex analysis to separate out the different flaw distributions.

For sample sets with a narrow distribution of strength values, the Weibull modulus will be high – being of the order 50 for freshly drawn silica fibers, whereas for most glasses it will typically be between 2 and 10, indicating a broad distribution of strength values.

The practical problem with any statistical distribution of strengths is that the distribution measured on a new set of glass articles, or laboratory samples, is not necessarily representative of components that have been in use for some time. Proof testing in which all components are subjected to a certain stress level, which ensures that all components can survive this particular minimum stress level obviously can guarantee this performance only before subsequent handling and use. Unless carried out in an inert environment, such testing may actually compromise the strength of the articles before use, if stress corrosion then takes place during the proof test (see Section 5).

6 Chemically Assisted Crack Growth – Stress Corrosion

Fundamentally, fracture involves the breaking of chemical bonds. Thus, direct chemical attack on stressed bonds can result in crack growth, in a similar fashion to sufficiently high applied stresses; the significant difference is that the chemically assisted crack growth is usually very slow, with velocities lower than 1 mm/s; for comparison, the fast fracture normally experienced when a soda-lime-silica glass is broken reaches 1.5 km/s. The slow crack-growth process is referred to as subcritical crack growth and the process causing it is referred to as *stress corrosion*,

a term to be preferred over *static fatigue* because fatigue actually implies cyclical loading.

In silicate glasses, such chemically mediated crack growth can occur in the presence of atmospheric water. The reason is that strained $-\text{Si}-\text{O}-\text{Si}-$ bonds are more susceptible to nucleophilic attack by water, which breaks the linkage between adjacent silica tetrahedra by giving two disconnected $-\text{Si}-\text{OH}$ groups that relieve the local strain (Chapter 5.11). Strained $-\text{Si}-\text{O}-\text{Si}-$ bonds are present at any crack tip that is under some level of applied stress and will also be present in rings that contain fewer than six silica tetrahedra. The rate of crack growth as a function of the applied stress-intensity factor is shown schematically in Figure 9 where it appears that there is a certain minimum stress intensity level, K_{Ith} below which cracks do not grow. The presence of this threshold intensity factor for stress corrosion is subject to some debate. A number of different experimental techniques have been developed to measure K_{Ith} , which do not always give consistent results; typically, the values of K_{Ith} are between 25 and 33% of the fracture toughness. Above the threshold region, the crack growth velocity arising from direct chemical attack depends on the applied stress-intensity factor (Figure 9, region I). As suggested by Eq. (5) for a given applied stress, the stress-intensity factor at a crack tip usually increases with the crack length, hence the crack velocity also increases. Eventually, the crack becomes sufficiently long that the rate of chemical attack is limited by diffusion of water to the strained bonds at the crack tip so that the crack velocity reaches a plateau (Figure 9, region II). Finally, the crack becomes so long that the applied stress-intensity factor becomes equal to the fracture toughness: the transition to fast fracture occurs, the crack then rapidly accelerating to its terminal velocity (Figure 9, region III). Additional phenomena such as alkali diffusion under the local stress gradients around the crack tip may also occur around the growing crack tip, further affecting the stress corrosion chemistry [20].

In the literature, either an exponential function is fitted to the crack velocity data in region I

Figure 9 Schematic diagram of subcritical crack growth rate versus applied stress-intensity factor for silicate glasses.

$$\nu = \frac{da}{dt} = A \exp \left(n \frac{K_I}{K_{Ic}} \right), \quad (13)$$

implying the log-linear plot exemplified in Figure 9; or a power-law function is fitted

$$\nu = \frac{da}{dt} = A_p K_I^{n_p}, \quad (14)$$

implying that Figure 9 should be a log-log plot. In Eqs. (13) and (14), A , A_p , n , and n_p are empirical constants, although in principle both A and A_p should be related to the relative humidity and to an activation energy. In Eq. (14), n_p is found experimentally to take typical values between 15 and 50 depending on composition. In principle, Eq. (13) should be preferred as its parameters lend themselves to clearer physical interpretation [19, 21]. However, Eq. (13) lacks a closed-form solution for the commonly used conditions of constant stress-rate test so that Eq. (14) is often used instead. We will now assume that the critical crack length for failure is much greater than the initial crack length. For a constant stress-rate test at a loading rate, $\dot{\sigma}$, Eq. (14) then predicts that the mean failure stress, $\bar{\sigma}_f$, is given by

$$\bar{\sigma}_f^{n+1} = \frac{2\dot{\sigma}\bar{\sigma}_{\text{inert}}^{n_p-2}(n_p+1)}{A_p C^2 \pi K_{Ic}^{n_p-2}(n_p-2)}, \quad (15)$$

where $\bar{\sigma}_{\text{inert}}$ is the mean strength measured under inert conditions. In other words, Eq. (15) indicates that a log-log plot of $\bar{\sigma}_f$ versus stress rate should be a straight line with a positive slope. Although more convenient for constant-stress test methods, Eq. (14) tends to give overly optimistic results compared to Eq. (13) when used for extrapolated lifetime predictions.

7 Improving the Practical Strength of Glass

7.1 Residual Stresses – Thermal and Chemical Tempering

Increasing the practical strengths of bulk glasses is widely seen as desirable as it should, in particular, allow the production of lighter weight glass articles and, thus, lower production costs. One can achieve improved glass strengths by inducing compressive surface stresses so that K_{rs} in Eq. (8) is positive or by some types of surface coating that either prevent flaw formation or overcome pre-existing flaws.

Surface compressive residual stresses may be induced in glasses by two primary means – thermal and chemical tempering (Chapter 3.12). In thermal tempering, the glass is heated above T_g and then rapidly cooled, commonly by jets of air. This process can achieve maximum surface compressive stresses (σ_c) of the order of 100 MPa and can only be usefully applied to relatively simple geometries. Thermal tempering has therefore found its major use in the flat-glass industry, although it was originally discovered in the production of the rounded Prince Rupert drops (Chapter 10.11) and is also used on some glassware. Although the exterior of thermally tempered glass is under compression, the interior is necessarily under compensating tension with the maximum tensile stress being of the order of $\sigma_c/2$; the stress distribution is often taken to be parabolic through the glass thickness (see Figure 10a). For a parabolic stress distribution, the compressive layer depth is ~21% of the glass thickness, t , the compressive stress acting over a typical surface crack may be taken as being approximately constant and hence the residual stress term in Eq. (8) is given by

$$K_{rs} = 1.12\sigma_c\sqrt{\pi a}. \quad (16)$$

Figure 10 Thermally tempered glass. (a) Parabolic thermal tempering stress distribution; (b) typical fracture pattern.

As a result of the high interior tensile stresses, a crack that begins to grow and penetrates the interior has so much excess energy that it bifurcates many times to produce characteristic small fragments (see Figure 10b). These characteristic small fragments pose a significantly lower risk of severe injury than the large shards typically produced during the fracture of annealed glass, which is why thermally tempered glass is also known as safety glass. The high interior tensile stresses in thermally tempered glasses can also lead to failure from an interior defect if nickel sulfide or other inclusions are present in the glass (Chapter 3.12).

Chemical tempering involves thermally assisted ion exchange of a smaller ion by a larger one in a molten salt bath at a temperature below T_g to minimize stress relaxation during the process (Chapter 3.12). Most commonly, sodium ions in the surface of the glass are replaced by potassium ions. As a diffusion-based process chemical tempering is much slower, and more expensive, than thermal tempering, but yields much greater surface compressive stress levels, over a (case) depth of tens to a few hundreds of microns and thus very high degrees of strengthening. In this case, the residual stress distribution varies rapidly with depth so that calculation of the residual stress term in Eq. (8) has to take this effect into account. Glass compositions can be selected to optimize the ion exchange process, which has the additional advantage of being applicable to very thin glass. As a result, chemical tempering is now widely used to produce thin display glass with a very high-strength.

7.2 Coatings

Coatings applied to the surface of glass can have beneficial effects on mechanical properties (Chapters 6.7 and 8.1). Practical coatings essentially fall into two types – those that help prevent damage and those that overcome pre-existing damage. The former include the two-layer acrylate coatings that are applied to newly drawn silica-fiber optics as well as the hot- and cold-end coating combinations applied during container glass production (Chapter 6.4). Coatings that overcome pre-existing damage are flaw filling and include sol–gel and epoxy-based systems. The acrylate coatings on fiber optics are thick enough to prevent contact damage (softer coatings have to be relatively thick to sufficiently reduce the effect of contact stresses [22]), while hot- and cold-end coating systems increase the lubricity of the glass surface thereby reducing the extent of subsequent contact damage but not preventing it (and not overcoming any contact damage arising from earlier in the production process).

Sol–gel-derived silica and epoxy-based coatings have been demonstrated to overcome pre-existing damage in glass. These strengthening coatings must have low

enough viscosities on application to penetrate flaws and they also need to develop a good chemical bond with the glass. For an epoxy-based system, Hand et al. [23] showed that residual stresses developed, because of thermal expansion mismatch, inside a well-bonded coating penetrating pre-existing defects could explain the improved strength of the coated glass. For solvent- and water-based coating systems, these stresses were calculated to be about 35 and 90 MPa, respectively. More recently, Briard et al. [24] have attributed a similar level of closure stresses in an organosilane coating system to the elastic response of the material bridging the crack. Much of the work on demonstrating strengthening coatings has been conducted on glass samples containing relatively large, deliberately introduced, controlled defects. It is therefore notable that the recovered strengths remain well below the theoretical values, implying that only larger flaws are successfully penetrated by the coatings [25], which is not entirely surprising given that strength-controlling defects are often not optically resolvable. In addition, the application conditions needed for flaw penetration means that such strengthening coatings tend to be too thin to prevent subsequent contact damage [22].

8 Perspectives

Glasses are brittle, flaw-sensitive materials that under normal conditions achieve strengths that are only a small fraction of their theoretical values. Preventing contact damage during production, as is the case with the drawing of fiber optics from a preform (Chapter 6.4) and the Corning fusion overflow process for flat glass production (Chapter 1.4), combined with suitable coatings or ion exchange can be and is used to achieve high practical strengths for high-value end applications. Thermal tempering may be used to increase strength (and safety) for some window applications, although in others laminated systems are preferred. The stiffness associated with the relatively thick sections of conventional glass windows is often utilized from a structural design perspective (Chapter 9.1), but adds significant weight in transport applications whereas users are looking at ways of significantly reducing weight. Weight reduction is also a significant concern for containers and glassware, where glass is competing with polymers, and thus economic methods of achieving consistently high strengths for these applications are still being sought. Although the mechanical properties of glasses vary with composition [3, 12, 14, 15], compositional modifications on their own are only likely to produce limited benefits. If they can be used to optimize other processes such as ion exchange, however, then more substantial gains in mechanical properties are

achievable. Thus, at the time of writing, the fundamental challenge for the bulk glass industry (and thus a major challenge for glass research) is to find a way of producing consistently stronger glass products with a high Weibull modulus, enabling thinner glassware, containers, and windows, while keeping costs down to a manageable level.

3.12

Strengthening of Oxide Glasses

K. Stefan R. Karlsson¹ and Lothar Wondraczek²

¹ RISE Glass (Former Glafo), Built Environment Division, RISE Research Institutes of Sweden, Växjö, Sweden

² Otto Schott Institute of Materials Research, University of Jena, Jena, Germany

1 Introduction

Most oxide glasses are weak in bending and tension as compared to many other materials. Their strength can nonetheless be increased through various routes. Strengthening of glass is alternatively called toughening, tempering, or hardening. While nowadays widely employed technologically, it remains an important topic also on research and fundamental levels as glass keeps finding new applications for which improved mechanical properties are needed either directly or indirectly, i.e. to reduce the amount of material used and, thus, to lower weight. In this way, one can reduce CO₂ emissions, save fabrication costs, lower transportation expenses (which are particularly important for architectural application), and make handling of glass products easier. As discussed in Chapter 3.11, the practical strength of glass is only a small fraction of the theoretical limit because fracture always starts from flaws that are inevitably produced at the surface during fabrication or use. Varying widely, the severity of these defects depends to a large extent on the effective surface area and also on postproduction treatments of the glass products. When a glass sheet is mechanically cut, it is, for example, severely damaged by edge surface defects.

Increasing the strength of glass is currently achieved in three general ways, namely, (i) elimination or neutralization of existing flaws; (ii) prevention of flaw formation; and (iii) improvement of the strength of glass, which contains surface flaws, by introducing residual surface compressive stresses (see Figure 1). Typical examples of the first kind are the various polishing techniques used to

smooth the surface, e.g. chemical-mechanical polishing (CMP), etching (chemical), fire/flame, laser, and fluid-jet polishing. The second group includes most types of coatings, such as sol–gel or epoxy products whose purpose is to protect the glass surface. Because coatings partially can fill surface defects, they are in addition an example of the third kind of processes that mainly comprises thermal and chemical strengthening.

In the present chapter, these methods will be successively described, the basic principles of fracture being described in Chapter 3.11 on mechanical properties. As a convenient starting point, the main features of thermal and chemical strengthening are summarized in Table 1 whereas their strengthening characteristics are listed in Table 2 for soda-lime-silicate glass used in buildings. There are of course cases where combinations of different methods have been used, but such combinations have not received widespread commercial attention yet. As briefly stated at the end of this chapter, there is also a fourth group; it aims at improving the intrinsic strength of glass through a control of its structural anisotropy.

2 Strength and Stresses

The practical (or usable) strength of oxide glasses [2] is an extrinsic property, i.e. it depends to a lesser extent on glass composition than it does on the surface characteristics and geometry. Because it also varies from one glass piece to another, one is advised to evaluate glass strength by performing a number of rupture tests and make fits to the data with a normal or Weibull statistical distribution (Chapter 3.11). Typically, one needs at least 10 tests to determine an indicative strength value and more than about 30 to determine the characteristic strength of a given product. Several methods may be used, which can

Figure 1 General mechanism of residual surface compression increasing the fracture strength.

be divided into bending- and impact-strength tests. The former involve two-, three-, or four-point bending or ring-on-ring test whereas the latter measure the ability of the material to absorb the impact energy of a falling object that is typically released by a dropping ball or a pendulum hammer.

The different tests are best suited for different products, e.g. two-point bending for glass fiber or thin glass sheet and four-point bending for architectural glass (EN1288-3). If one wishes to eliminate edge effects on the strength, then the ring-on-ring test is performed according to EN1288-2 or EN1288-5. Besides, different methods

Table 1 Comparison of thermal and chemical strengthening ("ion stuffing" process) [1]. Note that for chemical strengthening the characteristics depend on the ion-exchange treatment parameters as well as the treated glass.

Property	Thermal strengthening	Heat strengthening	Chemical strengthening
Maximum strength	120–400 MPa	70–150 MPa	150–1000 MPa
Residual surface compression	90–150 MPa	35–55 MPa	100–900 MPa
Core tension stress	50–80 MPa	20–30 MPa	20–60 MPa
Thickness of surface compression layer	Approximately 20% of the glass thickness	Approximately 20% of the glass thickness	Thin surface compression (normally <100 μm) unless treatment time lengthened
Treatment temperature	C. 75 °C above T_g	C. 75 °C above T_g	C. 100 °C below T_g
Mechanical treatment after strengthening	No cutting or drilling is possible	Cannot be safely cut	Might be cut or drilled or ground depending on the internal tension
Cost	Less expensive	Less expensive	More expensive (about 2–6 times)
Glass thermal expansion	The higher the better strengthening (e.g. $\alpha = 9 \times 10^{-6} \text{ K}^{-1} \gg 150 \text{ MPa}$ while $\alpha = 3 \times 10^{-6} \text{ K}^{-1} \gg 50 \text{ MPa}$ residual surface compression)	In the range of 6–9 to have a beneficial strengthening effect	Not important
Optical distortion	Heating and cooling must be carefully controlled to avoid distortion	Heating and cooling must be carefully controlled to avoid distortion	No significant distortion of ware
Spontaneously fracture	Yes	No	No
Time for treatment	Short time required (minutes)	Short time required (minutes)	Long time required (hours)
Sample thickness	Minimum 2 mm	Minimum 2 mm	0.2–15 mm
Shape	Not applicable to shapes where all surfaces are not freely accessible to chilling medium	Not applicable to shapes where all surfaces are not freely accessible to chilling medium	Applicable to unusual shapes as long as the glass surface can be in contact with the molten salt
Glass compositions	Applicable to most glasses	Applicable to most glasses	Alkali-containing glass compositions
Strengthening of abraded samples	No	No	Yes

Table 2 Characteristic tensile strength (95% confidence and 5% fractile) for glass in buildings. Average values of tensile strength can be up to ~70% higher.

Type of flat glass	Characteristic strength	Standard
Annealed window glass	45 MPa	EN 572-2
Heat-strengthened float glass	70 MPa	EN 1863-2
Fully tempered glass	120 MPa	EN 12150-2
Chemically strengthened float glass	150 MPa	pr-EN 13474-3

may give different characteristic strength values. For instance, one generally determines a higher characteristic strength in three- than in four-point bending experiments unless a proper correction is made for the position of the fracture origin. Besides, abrading samples prior to subjecting them to a bending strength test is advised if one wishes to compare the effects of different strengthening treatments.

Internal stresses play a critical role in the intrinsic strength of a glass. Their measurements are thus of basic importance. They rely on the fact that optically transparent materials such as most oxide glasses exhibit the phenomenon of stress birefringence [3]: if planar or circular polarized light passes through a glass with residual stresses, the light wave is split into two other waves whose planes of polarization are parallel to the local principal stress directions. The two light waves travel through the glass at different speeds, which gives rise to a phase difference related to the in-plane stresses, governed by the stress optical coefficient of the material, i.e. by its stress dependence of the linear refractive index. Residual stresses in oxide glasses can therefore be determined from birefringence fringes measured by photoelastic methods such as differential surface refractometry (DSR), grazing angle spherical polarimetry (GASP), scattered-light polariscopy (SCALP), or polarization microscopy with a compensator such as of the Babinet, Babinet-Soleil, or Berek type. The stress profiles of strengthened glasses are important information as they control not only the ultimate strength of the material but also the pattern of fracture. Information such as the magnitude of compressive and central tensile stresses as well as the depth of the compressive layer can be studied in photoelastic measurements. These methods will likely be further improved as digital imaging, image processing, and new light sources become more readily available. It is also worth mentioning that finite element modeling (FEM) can be used to predict stress profiles although significant limitations still affect the boundary conditions of the available FEM models.

3 Elimination of Surface Flaws

3.1 Polishing

There are many different methods to compensate, avoid, or neutralize surface defects. All have in common that they aim at smoothing the surface and reducing the effective defect size, but they all suffer from the fact that the strength improvement is only temporary if the glass is left unprotected after treatment. Traditional methods operate on the material at room temperature. CMP has long been a common route whereby the glass surface is polished by different slurries or plates containing abrasive (granular) material of different grain sizes. As indicated by its name, the method actually involves both chemical and mechanical mechanisms because the abrasives are applied to the glass in combination with liquids, such as water or oils, not only to avoid overheating but also to induce chemical reactions. The chemical reactions can be described in terms of erosion/corrosion mechanisms, e.g. diffusion reactions, glass dissolution under load, adsorption rate of dissolution products on the polishing grain, the rate of silica redeposition onto the glass surface, and the aqueous corrosion rate between particle impacts [4]. Depending on the target application, polishing is usually performed step by step from rough to fine with smaller and smaller abrasive grains. From coarse to fine, typical polishing abrasives are SiO₂ (sand), SiC (silicon carbide and carborundum), Al₂O₃ (corundum), CeO₂ (cerox), and diamond paste, cerox being in fact the major abrasive used because of its relative softness which provides high surface quality and relatively high material removal rate combined with a low degree of inherent scratching. For safety (and also aesthetic) reasons, it is common to grind/polish mechanically the edges of flat glass to render them plane, chamfered, or round. This operation is widely performed not only in the flat-glass industry but also for art and optical glasses.

Etching is a purely chemical process whereby polishing results from dissolution of the glass by aqueous solutions of hydrofluoric acid (HF), one of the few acids that efficiently dissolves silicates at room temperature. For pure SiO₂, the reactions are

and

As indicated by these reactions, attack by HF is not strictly an etching process, but rather a chemical dissociation reaction.

Owing to its broad versatility and very high reproducibility, HF etching has traditionally been used in the art-glass industry for producing extra clear and also matt or frosted surfaces. But the process is not always efficient to

remove surface defects and improve the strength of glass because of its relative slowness. In addition, HF is very toxic so that extreme precautions need to be taken when it is handled. In view of its toxicity and resulting problems in the work environment, it is now less used.

In the art-glass industry, etching has been complemented or partly replaced by fluid-jet polishing performed with versatile robots. Hereby, fluid-jet polishing is a generic term for many different techniques that all rely on the high-velocity jet formed when a pressurized fluid passes through a small nozzle. If the jet is projected onto a glass, some matter is removed by erosion to yield a smoother surface or, more often, to cut it more smoothly than by traditional mechanical means. Water or gases are generally used but abrasives can be added to the fluid to tailor the rate of material removal. Depending on the nature of the fluid, one distinguishes abrasive-jet (e.g. sand-blasting), abrasive-water-jet, and abrasive-slurry-jet polishing. Water-jet technology or hot-air jet technology can also be used to cut glass [5]. With water jets, both abrasive and nonabrasive cutting is possible. Hot-air jet cutting is based upon thermal-stress cleavage, where a scratch or a shallow cut is needed so that the hot-air jet causes thermal stresses to fracture the glass alongside this pre-scratch.

Other polishing techniques rely on self-healing of a glass rapidly heated up such that the nominally defect-free surface associated with fire polish is obtained. At temperatures higher than the transformation range, flaws are spontaneously eliminated through reduction of the surface area that results from minimization of the surface energy of the molten glass. Fire/flame polishing is frequently used in the production of household glass such as stemware and tumblers (Figure 2). The flame is most often oxidizing with a temperature of about 2000 °C such that the surface is quickly heated to softening temperatures in the 600–800 °C range. For stemware, fire/flame polishing is usually performed in three very fragile zones, namely, the junctions with the foot and the bowl, and the rim, which is especially vulnerable as it is cracked-off by thermal shocks produced either traditionally or with laser heating to ensure finer cuts.

For glass optical components that need a very fine polish, new, more sophisticated methods have been designed. Ion beam polishing, for instance, consists in a bombardment procedure with reactive ions (e.g. Ar⁺) at wide angles, leading to surface sputtering and, hence, flattening-out of surface roughness. Plasma polishing involves chemical reactions between reactive plasma and surface atoms of the glass. Magneto-rheological polishing process is based on magnetic manipulation of magneto-rheological slurries, which is controlled via computer algorithms. Finally, elastic emission machining

Figure 2 Flame polishing of the rim of stemware in a glass production facility (Sandvik Glassworks, Sweden).

is very similar to abrasive polishing with the main difference that it is controlled numerically.

3.2 Laser Heating and Cutting

In advanced glass production, high-power infrared CO₂, Nd-YAG, or diode lasers are now used to polish or cut glass. For polishing, the process is relatively similar to fire/flame polishing because it reduces the viscosity of the glass surface where defects are removed. Although it is a fairly recent technique, laser cutting has become relatively widespread for both flat and household glass. It is even making mechanical means obsolete for thin glasses because of the dramatic reduction of defects along the created edges (Figure 3). Another advantage is that it is a clean process compared to mechanical scribing, as it typically does not create debris.

As summarized in Table 3, laser cutting can be performed in different ways. One is very similar to the mechanical method in that a laser is used to scribe the glass surface before the second step of breaking [5].

Figure 3 Contrast between the cracked edge of a 4-mm thick mechanically scribed float glass (a) and the smooth edge of a 2-mm thick laser-cut sample of another float glass (b). Special thanks to MDI Advanced Processing GmbH for providing us with the latter sample.

Cutting speeds of 1–2 m/s have been achieved with an Ar laser. Thermal-stress cutting is another method, suitable glasses thinner than 1 mm, whereby a crack is first initiated with a diamond tip or an ablation laser. The IR laser then locally heats the material in a predetermined path and builds in this way high compressive stresses inside it, which prevent the crack to propagate. A coolant water-jet beam then follows the path of the IR laser and turns the compressive stresses into high tensile stresses that cleave the glass.

With a third process, the glass is cut solely by laser ablation with the green or UV beam of (excimer) lasers, which can also chamfer the glass edge at the same time. A fourth method called filament cutting makes use of the shorter pulses of a green laser, thereby creating less heat than longer pulses and reducing the width of the heat-affected zone (HAZ). Filament cutting provides high edge-surface

quality at cutting speeds of about 0.5 m/s, which is still slow compared to mechanical scribing typically made at a rate of about 3 m/s. In summary, laser glass cutting is still a rapidly evolving technology that performs well for thin glasses, whose main disadvantage currently is the high investment cost of the instrument for a relatively slow cutting speed.

4 Thermal Strengthening

4.1 Compressive Stresses

Thermally strengthened glass is widely used in architectural applications (Chapter 9.1), in the transportation sector (Chapter 9.2), and is also very common for covers of photovoltaic and concentrated solar power modules (Chapter 9.4) with the important practical constraint that, because of its high strain-energy content, the material can no longer be subjected to any mechanical treatment. Thermal strengthening of containers and drinking ware is less common but is developing (Chapter 1.5) as the process is quick and not very expensive so that its cost may be offset by the various advantages resulting from weight reduction.

Thermal strengthening relies on the fact that glass, like most brittle materials, is strong in compression and weak in tension. In this process [6], the glass is rapidly quenched with dry or humid air, which is quite generally pressurized. Because the glass surface cools down and contracts more rapidly than the interior, the interior finds itself in compression whereas the surface is in tension. At T_g , the glass surface becomes an elastic solid while the hotter interior still is a viscoelastic body that can undergo structural and stress relaxation [7]. As the glass continues to cool down, the interior contracts and the glass surface are then placed in a state of compression by the contracting interior whose tensile stress eventually balances the

Table 3 A comparison of different laser cutting methods [5].

	Laser scribe and break	Thermal-stress cutting	Laser ablation	Filament cutting
Edge quality	Causes edge damage	Good	Poor surface finish	Relatively good
Scribing	Initiation required	Initiation required	Not required	Initiation required
Drawbacks	Balance of scribe and break speed	Precise thermal and stress fields needed	Deposits of melted glass	Difficulty to control the depth of microcracks
Drawbacks	Laser focused on a narrow line	Difficult to control at high speeds	Grinding/polishing necessary	Polishing may be necessary
Process steps	Two	Single	Two	Multiple scanning
Thickness range	Thin/thick glasses	Thin glasses	Thin/thick glasses	Thin glasses

compressive stresses at the surface. With the assumption of a truly parabolic residual stress profile, which is borne out by experimental data (Figure 4), one finds that the central tensile stresses are approximately half the value of the compressive stresses at the surface.

4.2 Tempering Processes

In practice (Figure 5), the glass is cooled within a few tens of seconds from a temperature higher than $600\text{ }^{\circ}\text{C}$ to ambient. During the first seconds, the temperature drops at the surface by more than $150\text{ }^{\circ}\text{C}$. Starting from a temperature T_0 about $75\text{ }^{\circ}\text{C}$ higher than T_g is of major importance in an industrial process: if T_0 were too low, it would cause the glass to fracture upon cooling whereas, if it were too high, the glass would not be stiff enough so that it would be marked by the rollers when beginning to cool down. Importantly, the rapid cooling required must be relatively uniform to prevent too large tensile stresses from developing at the surface. For this reason, all surfaces must be freely accessible to the air jets when strengthening glasses with complex geometries. Thermal strengthening thus depends on the thermal expansion of

the glass, the quality of the parent glass, the maximum cooling rate practically achievable, and the availability of freely accessible surfaces. Soda-lime-silicate glass is most commonly used; float glass being, for instance, standardized by EN 572-2 for architectural applications.

Theoretically, the highest cooling rates allow highest compressive stresses to develop in the glass surface and thinner glass to be strengthened. Upon too fast cooling, however, the initial thermal gradient and surface tensile stresses can become so large as to cause glass fracture. The temporary tensile stresses which develop at the glass surface during cooling from the initial temperature (T_i) to T_g ($\Delta T = T_i - T_g$) can be estimated from Eq. (3) [8],

$$\sigma_i = \frac{E\alpha}{1-\nu} \Delta T = \frac{E\alpha}{1-\nu} \left(\frac{d^2 R}{8k} \right), \quad (3)$$

where E is the elastic modulus, ν is Poisson's ratio, α is the thermal expansion coefficient, d is the thickness of the glass, k is the thermal diffusivity, and R is the cooling rate (noteworthy, all in the range immediately above T_g). As seen from Eq. (3), the amount of temporary tensile stress depends to a large extent on the thickness and on the cooling rate; however, thermal relaxation also matters.

Figure 5 Process scheme of the thermal strengthening process (AT = ambient temperature).

For stress relaxation, the following estimation may be used:

$$\sigma_r = \sigma_i \exp(-\tau E / 6(1-\nu)\eta), \quad (4)$$

where σ_r is the relaxed tensile stresses, τ is the observation time, and η is the viscosity. With conventional cooling rates, the temporary tensile stresses are about 40 MPa. For thinner glass, greater cooling rates are needed. In Figure 6, the developed stresses of a thermally strengthened soda-lime-silicate glass are modeled for a given cooling rate, illustrated as a function of glass thickness. As the glass becomes thinner, the cooling rate is not sufficient to develop the same magnitude of stresses. To demonstrate the importance of the cooling rate, the residual stress profiles are also plotted (Figure 7) as a function

Figure 6 Calculated residual surface and central stresses as a function of the glass thickness for a given cooling rate of a typical soda-lime-silicate glass.

Figure 7 Residual stress profile for a given thickness as a function of cooling rate, t_0 is the critical time, i.e. the time that it takes for the center of the glass to be the same temperature as the surface. For a 4 mm glass, t_0 is 4.041 seconds for a typical soda-lime-silicate glass.

of cooling rate for a 4 mm soda-lime-silicate flat glass. As the cooling rate decreases, or the critical time to cool from T_i to T_g increases, the developed compressive stresses in the surface becomes lower.

4.3 Strengthening Limitations

In general, therefore, there is a critical limit to the thickness of the glass that can be thermally strengthened by conventional processes. Commonly, 3 mm was considered minimum but a strengthening process for 2 mm or thinner glass has recently been developed. In this state-of-the-art process, the rollers are replaced by gas flotation systems in the furnace (e.g. the HZL technology of the LiSEC group and Glaston's GlastonAir™). In this respect, eliminating the ceramic rollers is very important because they readily introduce surface defects onto the glass such as roller waves or scratches, thereby increasing the susceptibility to fracture, and also may act as heat sinks during quenching.

Fully thermally strengthened glass is also called *safety glass* because it fractures into small fragments, which are in general much less sharp and dangerous than the large dagger-like pieces of broken annealed glass. This important feature results from the balancing tensile stresses in the interior, i.e. the large amount of strain energy. When thermally strengthened glass fractures, the strain energy is rapidly released through the creation of the new surface of small blunt fragments. A smaller fraction is released as sound, heat, and kinetic energy in the fragments. The strength of thermally strengthened glass increases linearly with central tension whereas, as

Figure 8 A plot of the number of fragments per square centimeter as a function of the fourth power of central tension, data taken from [9]. The inset shows a fractured thermally strengthened glass, it is not linked to the data.

Figure 9 Typical “butterfly” fracture pattern (to the left) with the origin of a NiS particle (shown to the right). Special thanks to John Colvin, Glass Consultant, for providing the photos.

illustrated in Figure 8, the frangibility (strain energy) increases as the fourth power of central tension [10]. In contrast, a lower degree of strengthening is achieved for the standardized *heat-strengthened* glass, which is also thermally strengthened but with a slower cooling rate and lower central tensile stresses so that its fracture pattern resembles that of annealed glass.

Several standards have been developed for commercially used thermally strengthened glass in buildings, e.g. EN 12150 for fully thermally strengthened glass, EN 1863 for heat-strengthened glass, and ASTM C1048-12e1. They describe dimensions, fracture characteristics, flatness tolerances, and physical characteristics (such as thermal durability, mechanical strength, and iridescence) of thermally strengthened glass. The degree of thermal strengthening is also standardized. In Europe, according to EN 12150-1, the glass is fractured in a controlled manner and the number of glass fragments in a standard area is counted. The residual stress profile can be deduced from the number of glass fragments, typically it ranges from 0.6 to 1.6 numbers of fragments per square centimeter for fully thermally strengthened glass depending on the thickness of the glass. The degree of strengthening ensured by heat-strengthened glass (standardized in EN 1863) is characterized instead by an area/mass criterion for both small fragments and medium-sized fragments. There is also an ASTM standard, C1279, where the surface and edge stresses are standardized. It involves a nondestructive photoelastic measurement of the surface compressive stresses with the DSR, GASP, or SCALP techniques mentioned in Section 1, the surface compressive stresses are s .

4.4 The Problem of Nickel Sulfide

Fully thermally strengthened glass suffers from another major problem when nickel is introduced into the glass as a contaminant of the raw materials, most likely in the form of stainless steel fragments. In the glass melting process, nickel then reacts with sulfur impurities to form NiS inclusions whose size ranges from 0.05 to 0.6 mm. Under equilibrium conditions, nickel sulfide should transform below about 390 °C from a high-temperature

(α -NiS) to a low-temperature (β -NiS) phase. When the glass is rapidly cooled, however, the kinetics of the transition is too slow for α -NiS to transform into β -NiS. The α -phase thus remains metastable until, after a time that depends on thermal history and possible exposure to solar radiation, the transition eventually takes place irreversibly at ambient temperature. If the NiS is located in the central tension zone, the volume increase of 2–4% caused by this transition may then cause spontaneous fracture of the glass even when the inclusions are too tiny to be visible. A “butterfly” fracture pattern (Figure 9) may be observed in such cases. Owing to the importance of these inclusions, a standardized, heat-soak test (EN 14179, DIN 18516) has been designed to detect their presence. It consists in heating the glass for a minimum of two hours at 290 ± 10 °C, a temperature at which the NiS phase transformation is greatly accelerated.

5 Chemical Strengthening

5.1 An Expanding Method

Chemical strengthening is the other main process with which compressive stresses are generated in the glass surface. It is the term commonly used to describe the effects of *ion stuffing*, namely of $K^+ - Na^+$ and $K^+ - Li^+$ or $Na^+ - Li^+$ ion exchange in sodium- and lithium-bearing glasses, respectively. There is not a unique and generally accepted definition of chemical strengthening, however, because the same term also designates processes through which stronger glasses result from differences in thermal expansion coefficient between the surface and subsurface [1].

Chemically strengthened glass windshields for automobiles were already marketed in the 1960s by General Motors, but these were not a success, mainly for cost reasons, at the time the newly evolving float glass was being widely adopted (Chapter 1.4). From 1971, however, most spectacle lenses in the United States have been strengthened in this way to withstand the minimum impact-load conditions prescribed by the Federal Drug Administration. Whereas chemically strengthened glass found numerous applications in the air, naval, military,

automotive, locomotive, electronic, and architectural sectors [1], its more recent, extensive uses in electronic displays has made its presence more widely felt in the general public (Chapter 6.10). In recent years, this increasing demand has led large producers of specialty glasses to launch commercial products from float glass (Chapter 1.4), e.g. Schott Xensation™ series, AGC, Dragontrail™, or by the fusion downdraw process, e.g. Corning® Gorilla® Glass and NEG Dinorex™ series.

5.2 Ion-Exchange Diffusion

Ions are exchanged when a glass containing a rather mobile ion, A, is exposed to a concentrated source of another mobile ion B so that A ions diffuse out of the glass to be replaced by B ions from the source as described by the reaction

For cost and melt stability reasons, the source is typically a molten salt with which the glass interface instantaneously achieves a close contact (Figure 10). The reaction takes place under thermodynamic conditions such that the activation energy for the exchange reaction may be overcome and the kinetics of the reaction are fast enough to be acceptable from a practical standpoint.

In general, several ions can be exchanged through reactions that are kinetically described by Fick's laws for diffusion of equally charged ions. Referring to Frischat [12] for extensive information on these reactions, we will focus here on alkali exchange and dealkalization (i.e. replacement of alkali ions in the glass by hydronium ions).

The inward and outward diffusing ions have different sizes and should, therefore, have different mobilities in the glass. The more mobile ones will tend to outrun the less mobile, causing an internal electric field in the glass. This field slows down the former ion and accelerates the latter until both have equal mobilities. In general, this interdiffusion process can be described by an effective interdiffusion coefficient $\bar{D}$.

$$\bar{D} = \frac{D_A D_B}{\gamma_A D_A + \gamma_B D_B}, \quad (6)$$

where D_A and D_B are the diffusion coefficients of the two ions and γ_A and γ_B are the local ion mole fractions (Chapter 4.4). The ion-exchange interdiffusion coefficients can be determined in several ways if the proper boundary conditions for the solution of Fick's second law are applied.

Alternatively, one can enhance diffusion within the glass by other methods than thermal activation through the effects of an external electric field, of X-ray irradiation, or of microwaves. In general, enhancing interdiffusion also enhances thermal relaxation so that the result may not be useful when it comes to induce surface compressive stress. In addition, electric-field-assisted ion exchange is restricted to one side only of the glass piece, which may be disadvantageous for some applications.

5.3 The Ion "Stuffing" Method

Ion stuffing usually designates the most common chemical strengthening process. This batch process involves thermally assisted ion substitution of a smaller ion in the glass by a larger ion from a molten salt. By being

Figure 10 Schematic ion-exchange process (Source: Redrawn from [11])

Figure 11 Principal stress profile for a chemically strengthened aluminosilicate flat glass. The scale bar values are only indicative.

literally squeezed into the surface (Figure 10), the larger ion induces residual compressive stresses in the glass surface that seal defects as illustrated by the stress profile shown in Figure 11.

As ion stuffing is a diffusion-based process, it depends on temperature and time, being generally much slower and, therefore, about 2–6 times more expensive than thermal strengthening. The degree of compressive stresses induced by the incorporation of larger ions is mainly determined by the linear network dilatation coefficient whereas the depth of the compressive layer (DoL in Figure 11) is limited by the kinetics of interdiffusion [13]. Ions are usually exchanged for 2–24 hours at temperatures of at least 100 °C below the glass T_g in order to minimize stress relaxation during the process and to avoid any deformation caused by softening of the glass. As a result of ion exchange, the thermal expansion coefficient of the glass surface may be altered but the resulting effect is relatively small compared to that of “stuffing.”

Commonly, ion-stuffing strengthening involves Li^+ - or Na^+ -bearing glasses exchanged with Na^+ and K^+ , respectively. Notwithstanding their very high cost, Rb^+ or Cs^+ is not used because their still larger size would cause them to interdiffuse too slowly. The interdiffusion rate depends to a great extent on glass composition. The highest rates are generally found for alumina- or zirconia-containing glasses [11]. High enough alkali contents are also an important factor as chemical strengthening requires significant ion exchange whereas mixed-alkali glass compositions have a beneficial effect on the rate of interdiffusion [14]. Typically, glass compositions having a $\text{R}_2\text{O}/\text{Al}_2\text{O}_3 \approx 1$ molar ratio have a high rate of interdiffusion related to a low fraction of non-bridging oxygens (NBOs) [15]. Likewise, Varshneya [14] has suggested that higher compressive stresses can be achieved for glass compositions

having a greater network connectivity (along with in general a high Young modulus). The same applies to other minor constituents in the glass composition such as MgO .

The molten salt chemistry has also a strong influence on the kinetics of ion exchange. Whereas progressive contamination of the molten salt by the glass itself slows down the ion-exchange kinetics, there are indications that small salt constituents, such as alkaline earth ions [16] or hydroxide ions [17], have the same effect as a result of ion exchange with the glass for the former and of induced structural rearrangements or chemical reactions for the latter.

In summary, the efficiency of the ion-exchange process as well as the residual compressive stresses depend on several basic factors, the main ones being (i) the temperature dependence of the interdiffusion coefficient; (ii) the time of exchange; (iii) the nature of the glass-salt interface; (iv) the salt-bath chemistry; (v) the glass composition; (vi) the exchanging pair of ions; and (vii) the effect of temperature on viscous and structural relaxation.

Depending on these factors, the thickness of the compressive layer can be varied from tens to a few hundred microns. The tensile stresses in the interior typically range between 20 and 60 MPa and depend on the magnitude of the surface compression, the DoL, and the sample thickness. As to the fracture pattern, it depends on the same factors because it is a direct function of the magnitude of the tensile stresses in the interior. When fracture occurs, it usually yields fairly large sharp splinters but one can minimize the danger by sticking a thin plastic foil onto the glass surface. Although most chemically strengthened glasses can be cut either mechanically or with a laser, the created edges have much less strength since they are deprived of compressive stress.

Chemically strengthened flat glasses are standardized according to the norm ASTM C1422, which classifies the product by DoL and magnitude of surface compression. The ASTM C1422M-10 prescribes a standardized method to measure the stress profile of chemically strengthened glass with a polarization microscope and optical retardation compensation procedures. Chemically strengthened glasses are known to be very resistant to scratches in a way that depends on the DoL and on the magnitude of surface compressive stresses.

Finally, a more complex two-step ion-exchange process has been designed whereby the first is used to induce compressive stresses before the second either reintroduces the original ion or introduces a new one in the outermost surface layer. This two-step ion-exchange is used for making Engineered Stress Profile (ESP) glasses [18] whereby an ion such as K^+ is introduced in a sodium-bearing glass and at the end Na^+ ions are reintroduced. As a result, the surface is weak and cracks can grow and even become visible before they are arrested by the compressive zone somewhat beneath the glass surface, i.e. the glass does not depend on the size of the surface flaws. These ESP glasses were developed to be used for architectural purposes and designed to give a hint prior to catastrophic fracture occurs. It is noteworthy that similar processes have been developed for gradient index optics to produce a gradient in optical polarizability which leads to a gradient in refractive index.

Recently, work has been done on the strengthening effect of water treatment of glasses, which is another type of ion stuffing. Fett et al. [19] showed that considerable strengthening is obtained with the residual compressive stresses achieved as a result of an exchange of H_3O^+ for Na^+ ions. Likewise, Lezzi et al. [20] strengthened silica-glass and E-glass fibers by water vapor treatments of bent fibers, an effect explained in terms of H_3O^+ ion exchange and surface stress relaxation.

5.4 Differential Expansion Strengthening

Compressive stresses at a glass surface most simply result from the elastic resistance of the glass to volume changes induced by ion exchange, but they can also be created from temperatures above T_g from changes in the temperature derivative of volume, i.e. in the coefficient of thermal expansion (CTE). Upon cooling, the high-CTE layer tends to contract more than the low-CTE, putting the latter under compression. The simplest strengthening technique consists of cladding a low- over a high-CTE glass [11]. If the thermal-expansion differences are too large, however, very sharp stress gradients form at the interface so that the glasses are easily cracked off from each other. As with cladding, one can achieve the same effect by replacing sodium in the glass surface with

lithium in high-temperature ion-exchange strengthening. But the drawback of this process is that the glass surface generally becomes translucent within minutes because of surface crystallization whereas the strengthened glass may in addition deform under the high compressive stresses achieved. With TiO_2 as nucleating agent, the method is thus generally limited to special glass compositions such as aluminosilicate glasses in which beta-spodumene crystals precipitate as a result of Li^+ introduction in the glass via ion exchange.

Another type of strengthening technique relying on differences in CTE is dealkalization. It is based on the replacement of Na^+ by hydronium ions, H_3O^+ in the glass surface layer [12]. Dealkalization occurs when acidic gases such as HCl , SO_2 , or SO_3 react with sodium from the glass [21]. The surface layers are generally relatively thin although their thickness again depends on many factors such as temperature, treatment time, and glass composition. In general, dealkalization treatments affect the chemical durability to a larger extent than it strengthens the glass. It has previously been widely applied to container glass [22].

6 Strengthening by Coating

6.1 General Principles

One can also increase strength by coating the glass to protect chemically or physically its surface. Lacquers such as Teflon, Lexan[®], polyacrylates, and silanes represent an effective barrier and provide a chemically inert environment at the vicinity of the crack tip [23]. Mechanical protection is conferred by coatings such as SnO_2 and amorphous carbon that increase the scratch or abrasion resistance. In both cases, however, the strengthening mechanisms at work often remain insufficiently understood.

With coatings based on sol-gel and epoxy systems, one can alternatively reduce the effective lengths of cracks at the glass surface. Much of the work done on coatings that fill surface defects has been performed on deliberately abraded (e.g. sand-blasted) glass substrates containing relatively large controlled defects. As the recovered strengths remain well below the theoretical values, the conclusion is that only larger flaws are successfully penetrated by the coatings [24]. It is important, therefore, not only that the coatings have low enough viscosities on application to penetrate flaws but also that they develop a strong adhesion to the glass. For epoxy-based coatings, strengthening could be due to residual stresses arising from the thermal expansion mismatch of coating and closure of glass surface defects [25]. But most coatings used to fill surface defects tend to be too thin to prevent subsequent contact damage.

6.2 Sol-gel Coatings

The strength of glasses can be improved in different ways by sol-gel coatings, which fill surface defects, blunt crack tips, clamp crack sides, add a compressive stress to the surface, protect the material from fatigue, or form a barrier to moisture (Chapter 8.2). These coatings are typically used in the flat- or household-glass industries as well as in optical applications to yield reflective or antireflective surfaces, optical waveguides, and nonlinear optics. Most prominent are, for instance, tetraethoxysilane (TEOS)-derived silica coatings because they enhance the strength of silica glass by 120–130% whereas the strength of soda-lime-silica glass can improve by factors of up to three with polysilazane-derived coatings [1].

Sol-gel processes include two different methods, one based on gelation between colloidal particles in a sol and another on hydrolysis and polycondensation of alkoxide, nitrate, or oxychloride precursors (Chapter 8.2). In both processes, the solutions are dried and then sintered to form dense amorphous solids. In principle, any type of multicomponent oxide can be synthesized from the relevant alkoxides by the sol-gel process. For application onto glass substrates, the most common methods are dip, spin, spray, flow, roll, and capillary coating but electrophoresis and ink-jet printing are also used. The sol-gel coating process has several advantages such as simplicity, low processing temperature, low-cost capability for large surface areas, ease of application onto a variety of substrates, and suitability for forming uniform and homogeneous films with a sub-micrometer thickness or a high optical quality [1]. On the other hand, thicker coatings ($>1\ \mu\text{m}$) have the disadvantage of tending to crack, leaving areas open for contact damage. Examples of hybrid coatings also exist where inorganic sol-gel coatings are combined with a cross-linked polymer resin.

6.3 Other Coatings

Hot-end and cold-end coatings are commonly applied to glass containers to reduce surface damage of the glass (Chapter 1.5). Hot-end coatings typically consist of deposited SnO_2 or TiO_2 , which increase the abrasion resistance. Cold-end coatings are lubricants such as stearates, oleates, and polyurethanes; the increased lubricity reduces the extent of surface damage during packaging and transportation [23].

Acrylate coatings are traditionally applied to silica optical fibers immediately after drawing because they represent a good chemically protective barrier and they are also thick enough to prevent subsequent contact damage (Chapter 6.4). Acrylate coatings have also been investigated for strengthening of flat glass for which they have been demonstrated to be somewhat effective.

There are a vast number of different functional coatings based on methods such as chemical vapor deposition (CVD), particle vapor deposition (PVD), Sputter deposition, and pulsed laser deposition many of which influence the strength of the glass (Chapter 6.8). Guardian's coating DiamondGuard[®] is, for instance, a patented deposited carbon coating whose properties resembles those of diamond. It has been stated to increase the scratch resistance of the glass through the coating's low coefficient of friction.

Epoxy coatings can potentially be used in the flat-glass industry for edge-strengthening or large-area protective coatings, e.g. photovoltaic modules, automobile wind-screens. Besides, CVD and PVD coatings are widely used in the flat-glass industry, mainly, however, for functional purposes rather than for increasing the strength.

7 Perspectives

In recent years, strengthening of oxide glasses has tremendously improved even though the theoretical limits, which are higher than 20 GPa, are far from being approached. Much progress, in particular, remains to be made for thin glass, which raises many difficulties. In a general way, the first improvement to be achieved concerns the quality of flat glass as defects not only degrade strength but also strongly limit the ability to strengthen thermally glasses thinner than 1.5 mm because of cracking. Second, for thermal strengthening, the cooling rate needs to be increased to increase the fictive temperature of the material which might increase the risk of producing visible faults. As some glasses do not have the appropriate thermal expansion coefficients to be thermally strengthened, it could be possible to optimize the glass composition to remedy this problem and, thus, to increase the damage resistance of the glass. Another important issue is quality control. It would, for instance, be valuable to control reliably at a reduced cost the strengthening level by other means than fracturing the glass and counting pieces. Likewise, detection of NiS inclusions is of major importance so that an alternative to the heat-soak test could reduce costs considerably.

For chemical strengthening, the glass composition should be further optimized with respect to diffusion, stress buildup, and contact resistance of the glass itself, where the time needed for ion exchange remains the major limitation. Also a better structural understanding of the glassy network during the chemical strengthening process should help to understand better how to increase diffusion rates and the subsequent buildup of compressive stresses as well as how to decrease thermal relaxation as a the trade-off between high ion-exchange temperature

and low rate of stress relaxation. The salt-bath chemistry is also very important. Whereas a better understanding of the poisoning effect of minor contaminants is needed, the composition of the salt bath should be adjusted to each glass composition. Furthermore, innovations are needed to design automatic and online processes, which would make the process less expensive.

Coatings will likely be a future key in protecting oxide glasses from abrasion and possibly also for strengthening purposes. There are a vast number of coatings and a more complete overview of their effects for protective and strengthening purposes is needed. Furthermore, the strengthening mechanisms and the role of coatings need to be better understood.

As first discussed by Rawson [26], control of the structural anisotropy of glass is yet another type of strengthening. The glass surface defects has a major impact on the glass strength, however, increasing the intrinsic glass strength may also significantly influence the practical strength of glasses (mainly glass objects with lower effective surface area such as fibers). Recently, there has been some evidence that the drawing stress of continuous basaltic and E-glass fibers affects the structural anisotropy and that the tensile strength of the fibers can be correlated to the structural anisotropy [27]. Another example is the forming of heterogeneous phases in glass by femtosecond pulse laser irradiation [28]. There is yet much to be studied regarding controlling the structural anisotropy.

Radiation Effects in Glass

Nadège Ollier¹, Sylvain Girard² and Sylvain Peuget³¹ Laboratoire des Solides Irradiés, Ecole Polytechnique, CNRS, CEA, Palaiseau Cedex, France² Univ Lyon, UJM Saint-Etienne, CNRS, IOGS, Laboratoire Hubert Curien UMR 5516, Saint-Etienne, France³ CEA, Nuclear Energy Division, Bagnols-sur-Cèze Cedex, France

1 Introduction

That glass color can be affected by sun light was noticed by Michael Faraday (1791–1867) in 1824. This was the first reported observation on the effect of radiation on a glass property, as emphasized by Edmond Becquerel (1820–1891), an authority on luminescence [1] and the father of Henri, the discoverer of radioactivity. Much more severe radiation-induced damage was then detected very early in radioactivity studies when the Irish geologist John Joly (1857–1933) observed in 1907 *pleochroic haloes* around minerals emitting α rays (Figure 1) [2]. Joly understood that the sizes of haloes were proportional to bombardment duration. With the help of the famous Ernest Rutherford (1871–1937), he thus used the extent of damage as a very simple method to date rocks. Of course, the very long geological periods are not relevant to the limited lifetime of man-made products. In view of potentially much more severe conditions of use, a significant question is the ability of glasses to withstand high levels of irradiation either by photons ranging from ultraviolet to gamma or by particles such as neutrons, electrons, protons, and heavy ions.

Important applications include not only nuclear-waste storage in chemically complex glass matrices (Chapter 9.12) but also numerous optical devices. In photonics, continuous-wave or nanosecond-UV lasers used for Bragg gratings inscription are, for instance, used to develop high-speed and multiplexed links in germano-silicate optical fibers for data transfer and sensing. Likewise, the utilization of femtosecond lasers for the

design of 3-D optical components in bulk materials has become an active and promising field. Whereas glasses withstanding high levels of radiation are required for a large number of applications operating in radiation-rich environments, radiation-sensitive glasses are, in contrast, of major interest for detection and dosimetry according to the principles laid down by Joly and Rutherford [3].

In oxide glasses, the network is composed of a polyhedral arrangement of glass formers connected by oxygen atoms (Chapters 2.4–2.6). Radiation can affect the local- and medium-range orders of the glass network either by an accumulation of point defects generated by electronic collisions or, directly, by nuclear collisions that cause displacement cascades and, therefore, some modifications of the atomic arrangement (Figure 2).

Because glasses are metastable phases, the question also arises as to whether the absorption of energetic radiations can trigger transitions toward states of lower enthalpy. No general answer can be given, however, because radiation-induced phase transitions, such as crystallization, have not been studied in a systematic manner except for silica. The main effects investigated have been those of electronic and nuclear collisions on silicate and borosilicate glasses. These are so diverse, however, that reviewing them all would be far beyond the scope of this chapter. In the field of femtosecond lasers, modifications depend on glass composition and on too many laser characteristics (wavelength, pulse duration, repetition rate, etc.) to be addressed here.

Interest will focus instead on the effects of ballistic interactions (atomic displacements) and ionizing radiation. Point defects will be first presented and attention will also be paid to the resulting changes in the structure of the glass network along with their consequences on density and bubble creations. In view of the importance

of optical applications, irradiation effects on light attenuation, refractive index, and redox state of rare earth (RE) ions will then be dealt with. Finally, the mechanical properties will be addressed in the context of nuclear waste storage, and approaches for hardening glasses will be presented.

Of course, the magnitude and kinetics of the changes observed depend on the nature and energy of the radiation (e.g. X and γ rays, neutrons, protons, and heavy ions).

For quantification purposes, the dose (or fluence) has been defined as the total energy brought to a unit mass of the material of interest (e.g. silica) and is expressed in Gray (Gy) units, i.e. $1 \text{ Gy}(\text{SiO}_2) = 1 \text{ J/kg}$ of silica glass. The dose rate (Gy/s) then is simply the ratio between the dose and exposure time, whereas a former unit, the rad ($= 0.01 \text{ Gy}$), remains widely used especially in the space-research community.

2 Point Defects

Over the last 50 years, numerous studies have been devoted to the nature, generation, and bleaching mechanisms of point defects in pure and doped silica glasses. After having first been mainly experimental, these studies now strongly benefit from multiscale simulation tools (e.g. [4]). Their results have been useful to design optical lenses, windows, mirrors, or other devices made up of silica, either pure or doped, with elements such as Ge, P, F, B, or N to tailor refractive-index profiles in single- or multimode waveguides.

Point defects in silica can be generated either by conversion of precursor sites into optically active defects or by the rupture of bonds such as Si–O–Si. Sometimes called color centers, these defects are associated with absorption bands generally peaking in the ultraviolet and the visible even though a limited number of defects do absorb in the

Figure 2 Irradiation defects in silica glass (from [4, 5]). (a) Main intrinsic point defects: ODC (oxygen deficiency center), E' (silicon dangling bond), NBOHC (non-bridging oxygen hole center), POR (PerOxy radical), and STH1 and 2 (self-trapped holes type 1 and type 2). (b) Isochronal annealing curves for some of these defects (c). Figure 3 Radiation-induced mechanisms in silica-based materials upon exposure to different types of radiations (Source: Modified from [4]).

infrared. A fraction of these defects, either trapped electrons or holes, is also an emitting center. This feature accounts for the luminescence observed under irradiation, as depicted in Figure 3 for the defect structures and their associated optical absorption and photoluminescence bands [5]. Also shown in this figure is the slow decrease of the concentrations of some silica-related point defects upon thermal treatments in irradiated silica samples with either large or low amounts of hydroxyl groups. This evolution illustrates another important property of point defects, namely, their thermal stability that influences both their concentration and their kinetics of formation or annihilation under irradiation.

Numerous other parameters (Figure 4) determine the generation and bleaching efficiencies of the various point defects and, thus, control the radiation-induced attenuation (RIA) and its kinetics in terms of growth and dose dependence at the operating wavelength(s) of the application. Some of these parameters are intrinsic to the glass. This is of course the case of composition (including doping elements and impurities such as hydroxyl groups), stoichiometry, and, for example, the core and cladding sizes in fiber optics (Chapter 6.4). In silica-based glasses, phosphorus doping is particularly interesting because, even at concentrations as low as few thousands of ppm, it strongly increases the level of RIA in the visible and infrared via the creation of numerous kinds of point defects. Indeed, at least eight varieties of paramagnetic

Figure 4 Main intrinsic and extrinsic parameters defining the levels and kinetics of radiation-induced attenuation in optical glasses.

defects having been identified in phosphate glasses [6]. Investigations of alkali silicate, borosilicate, and fluoride glasses have also demonstrated the existence of specific point defects [7, 8]. Among the most important ones are the hole centers associated with B (BOHC), Al (AlOHC), and alkali ions M^+ , for instance, of the HC_1 type: $(\equiv Si-O \dots M^+)$.

The knowledge acquired about point defects allows for a better control of their generation mechanisms and for the development of radiation-hardened optical fibers [9] or optical glasses for lenses. Alternatively, the glass

manufacturing process can also be adapted to favor the generation and stabilization of defects in very sensitive dosimeters. The absorption or luminescence signatures of certain defects are then valuable to monitor large dose ranges or rates. Through its absorption band peaking at 1600 nm in the third telecom window, this is the case of the P_1 defect in phosphorus-doped glasses that makes possible distributed monitoring of doses from a fraction of Gy to 1 kGy(SiO_2) at CERN facilities.

3 Vitreous Phase Stability and Bubble Formation

3.1 Ionizing Irradiation

Two kinds of experimental approaches are followed depending on the electron energy and flux, and thus, on the dose to which a bulk glass is exposed. A dose as high as 1 GGy can be delivered in less than one minute by high-energy electrons in the 100 keV to 1 MeV range by a transmission electron microscope (TEM, cf. Chapter 2.3) but in one day by accelerators. The formation of oxygen bubbles is one of the major features observed under the high-flux irradiation conditions under TEM. Their nucleation and growth are controlled by the electron-beam flux and the irradiation temperature affecting the local glass structure, respectively, and by a breaking of bonds that enhance the diffusion mechanisms of alkali and oxygen atoms [10–12]. In other words, the intense ionization induced by a high electron flux likely causes an effective viscosity decrease due to bond-breaking processes, which in turn enhances alkali and oxygen diffusion and drives phase separation [13]. Through inter- and intra-atomic Auger de-excitation, electron-stimulated desorption (ESD) of alkali, oxygen, and silicon atoms or ions is another important mechanism that can modify local chemical compositions [14] and induce phase transformations. In borosilicate glasses (Chapter 7.6), phase separation, for instance, originates in the depletion of charge-compensating alkali cations and subsequent boron-coordination changes from 4 to 3 [12].

The integrated doses obtained under gamma rays with ^{60}Co or ^{137}Cs sources emitting at energies of 1.17 and 1.33 or 0.66 MeV, respectively, are generally of the order of 1 MGy. In a TEM study of γ -irradiated Na silicate glass, the formation of bubbles was observed, which was attributed to a radiolytic decomposition involving free sodium ions and molecular oxygen [15]. However, no bubbles were detected in a γ -irradiation study of the same glass, even at higher doses [16]. This disagreement illustrates the complexity of understanding the glass response and sheds light on the influence of the characterization of the γ -irradiated glass by TEM that can affect the global response depending on the conditions used

(electron-beam current, magnification and focus, time of electron-beam exposure, etc.).

Finally, lower-energy electrons in the keV range are produced in scanning electron microscopes (SEMs, Chapter 2.3) or electron microprobes (Chapter 5.1). But a major drawback then is the buildup of a negative-charge space caused by the stopping of primary electrons within the sample [10]. In turn, this effect translates into significant field-assisted alkali migration, i.e. in accumulation of alkalis where electrons are implanted and in depletion at the surface. Such modifications of the local glass composition make it necessary to consider the results obtained with care as they may interfere with the irradiation effects themselves.

3.2 Nuclear Collisions

The effects of nuclear collisions have mainly been studied in nuclear glasses either doped with short half-life actinides or bombarded by heavy ions. Of particular interest is the fact that actinide-doped borosilicate glasses do not undergo any phase separation or crystallization detectable by optical microscopy, SEM, and TEM upon exposure up to $10^{19} \alpha/\text{g}$, which would represent the dose received by a waste-storing glass over several hundred thousand years [17]. Likewise, no phase transformations have been observed upon external irradiations of oxide glasses with heavy ions, the only effects being the modifications of the glass structure described in Section 4.1.

For α decay, the possible formation of helium bubbles in actinide-doped glasses has also been studied from a combination of He infusion (i.e. equilibrium at defined T and P between helium gas and a solid) and He-ion implantation experiments along with in-pile irradiation with the $^{10}\text{B}(n, \alpha)^7\text{Li}$ reaction. The result is that bubbles can form when the number of He atoms exceeds that of the sites where they may fit [17], which represents a concentration of about 1–3 at % in borosilicate glasses [18].

4 Glass Network Evolution Under Irradiation

4.1 Structural Effects

Short-range order is very stable in silica glass, which means that Si remains fourfold coordinated regardless of the irradiation conditions [19]. In molecular dynamics simulations, the existence of some fivefold coordinated silicon atoms resulting from displacement cascades has nonetheless been reported [20]. Irradiation, however, affects medium-range order through modifications of angular distributions and ring statistics. In silica glass, a decrease of the Si–O–Si angle and an increase of the Si–O–Si angle distribution can be deduced from the shift

and broadening of the R-band in the Raman spectrum, respectively. The maximum observed decrease of -10° (angle of $\sim 135^\circ$) was obtained after neutron irradiation [19]. The ring statistics is also modified with an enlarged distribution in the irradiated glasses. These glasses contain more small-membered rings, as indicated by the increase of intensity of the D_1 and D_2 Raman bands and from molecular dynamics simulations results obtained on the effects of nuclear collisions [19, 20].

The structural evolution strongly depends on glass composition. In borosilicate glasses, for example, changes of boron and aluminum coordination from 4 to 3 and from 5 or 6, respectively, take place under irradiation as a result of either electronic or nuclear collisions [7, 17]. For both initially fourfold coordinated B^{3+} and Al^{3+} atoms, these coordination changes are due to destabilization of alkali charge-compensating cations, an effect likely associated with alkali migration under irradiation. The formerly charge-compensating alkalis then become network modifiers. They induce a decrease of the glass polymerization index unless they form clusters with other available alkali in their neighborhood, in which case the polymerization index can increase. Hence, the polymerization state of the glass can decrease or increase depending on glass composition and on the type of radiation–matter interaction involved.

Although modifications of local- and medium-range orders upon irradiation are certainly connected, no model currently accounts for the observed structural transformations and predicts their variations with composition. The effects of nuclear collisions have been more extensively studied in the last decade. The results obtained have suggested that the driver of the structural evolutions in both local- and medium-range orders could be associated with a local melting process in the displacements cascade zone, followed by a very high quenching rate step that freezes the glass structure in a higher enthalpy state. Therefore, a model of irradiation-induced vitrification involving ballistic disordering and fast quenching events has been proposed [21] (also called super-vitrification). It also explains the increase of the fictive temperature of the glass observed upon irradiation in a ^{244}Cm -doped borosilicate glass [22].

4.2 Density Effects

Compaction of silica glass under neutron irradiation was first reported in 1958 [23]. The density rate increase is first rapid and saturates with a maximum densification of about 3 at % (Figure 5). This saturation value is the almost the same for all kinds of irradiation (e.g. ions, neutrons, electrons, or UV photons) [19]. Compared with ionizing radiations, nuclear collisions are much more efficient with a saturation reached at $10^{21} \text{ keV}_{\text{nucl}}/\text{cm}^3$ as opposed to around $6 \times 10^{23} \text{ keV}_{\text{elec}}/\text{cm}^3$ for ionizing

Figure 5 Compaction of silica glass induced by neutron irradiation [22].

radiations [19]. Since high-pressure permanent compaction of SiO_2 glass begins at 9 GPa and reaches 21% at 25 GPa [24], the effects of irradiation are comparatively minor. The dose dependence of compaction obeys a D^n power law where n is $2/3$ for ionizing irradiation and close to 1 in the case of displacement damages [25]. Introduction of hydroxyl groups in pure silica first causes swelling at low doses and then densification. Similar trends are observed for alkali-silicate glasses where the relative contributions of swelling and densification depend on dose and irradiation type (ions or electrons). These more complex trends are due to diffusion of alkali ions under irradiation.

In borate systems, network compaction depends on glass composition and reaches up to a few percent as observed under a flux of neutron or gamma rays (kGy). It is caused by ring rearrangements induced by bond breaking between trigonal groups [26]. In borosilicate glasses, the density change seems to be controlled by the aforementioned structural changes mainly associated with lower boron coordination numbers and an increase of the fraction of non-bridging oxygens. Depending on glass composition, the density can either decrease or increase with irradiation but these variations are always lower than 3 at % [16, 17]. Like SiO_2 glass, compositions with low alkali content tend to shrink upon irradiation whereas glasses with a high alkali content in contrast tend to swell [16].

5 Optical Properties

6 RIA and Emission

As commonly observed, glass darkening or coloration is a striking example of RIA phenomena (Figure 6). As most of the defects absorb at high energies, the decrease of light transmission is usually larger at smaller wavelength, then

Figure 6 Radiation-induced attenuation in three samples of a fluorophosphate glass (S-FPL51 from OHARA) after irradiation with 6 MeV electrons at room temperature: (a) starting glass; (b) 600 Gy(SiO_2) dose; (c) 1 kGy(SiO_2); and (d) 5 kGy(SiO_2).

very large in the ultraviolet and visible domains (200–700 nm), and lower in the near-infrared range (700–2000 nm) [9]. A second noteworthy effect is the radiation-induced emission of light observed as scintillation of the glass, which of course degrades the signal-to-noise ratio. The emission originates either in particular from point defects (usually in the UV or visible domain) or from Cherenkov radiation (with an intensity peaking near 400 nm and then decreasing at higher wavelengths) [9]. This parasitic light is usually more intense at higher dose rates, and it is generally observed in glasses exhibiting low-to-moderate RIA.

Finally, radiations can induce build-in of charges in the glass, particularly under electron irradiation, initiating dielectric breakdown (Lichtenberg trees) and critical failure of the device. RIA is the limiting parameter in most applications of optical glasses and most optical fibers [9], obviously increasing in the visible domain with the accumulated dose (Figure 6). In practice, this phenomenon and its kinetics are not readily accounted for because they depend on both dose and dose rate, as well as temperature and the radiation type and energy. From the limited data sets available at high dose rates, however, empirical or semiempirical models have been set up to predict RIA as a function of dose and dose rate [9] that are currently used to estimate the vulnerability of fiber optics for space missions.

6.1 Refractive Index

When a large fluence of particles induces displacement damages, any densification is accompanied by changes in the internal stress, polarizability, and refractive index of the glass (Δn is in the 5×10^{-3} to 10^{-2} range for silica [19]). The effect on the last parameter is particularly impactful to optical systems in which it causes lens defocusing. It is also becoming a major issue when it affects the quality of the measurements and the spatial discrimination between events monitored with distributed fiber-based sensors relying on reflectometry techniques. This is particularly the case when environmental parameters, such as temperature and strain, are monitored under harsh environments through their impact of glass scattering signatures.

6.2 RE-Doped Glasses

Oxide glasses doped with trivalent RE ions are of prime importance as active and inactive components in optical and photonic devices, such as lasers or scintillators and phosphors. In these applications, the main irradiation effects are redox changes of the RE. When exposed to γ and X rays or electrons, the stable Eu^{2+} , Yb^{2+} , or Sm^{2+} states can, for instance, readily be formed by electron trapping in silicate, borate, fluorophosphate, or phosphate glasses, whereas Tb^{3+} and Ce^{3+} can be oxidized into Tb^{4+} and Ce^{4+} [27]. Under usual conditions, both Ce^{3+} and Ce^{4+} coexist in glasses where they act as traps of holes and electrons, respectively, limiting in this way the number of absorbing color centers. This is the reason why cerium is often introduced in glasses for limiting radiation effects on optical properties. Actually, doping with REs not only tends to reduce the number of radiation-induced point defects but also to modify the nature of point defects [28]. Unusual divalent states such as Er^{2+} or Nd^{2+} can also be stabilized when a hole center forms in the vicinity of the RE^{2+} . In association with an aluminum-oxygen hole center (OHC), Er^{2+} or Yb^{2+} ions then give rise to the optical-fiber photodarkening [29].

Another effect is the modification of the local environment of the RE (Yb^{3+} , Dy^{3+} , and Eu^{3+}). At doses higher than 10^4 Gy, it manifests itself as a decrease of the site symmetry for Eu^{3+} in different glassy matrices. Along with redox changes, such modifications of the local environment of RE ions cause variations of optical absorption and emission spectra (Chapter 6.2). In addition, the formation of point defects results in increases of the values of optical band gap and of the Urbach energy (i.e. the band absorption edge).

As for the lifetime of the excited states of RE ions, they are generally reduced under irradiation by up to 40% for doses higher than 10^8 Gy. This decrease is not a linear function of the dose as indicated by experiments performed with doses ranging from 100 to 10^9 Gy on glasses doped with Yb^{3+} and Er^{3+} , for which the lifetimes display a “plateau” between 10^5 and 5×10^6 Gy (Figure 7). Interestingly, the dependence of the lifetime on the logarithm of the dose is the same for trivalent RE ions and for phosphate, silica, or aluminosilicate glass matrices [28]. The presence of RE clusters in the glass does impact the

Figure 7 Effects of the radiation dose and Yb clusters on the $^2F_{5/2}$ lifetime of Yb^{3+} for two aluminosilicate glasses (Source: Modified from [27]).

lifetime of excited state (see Figure 7) in connection with the formation of point defects [28].

7 Effect on Mechanical Properties

It is mainly in the context of nuclear-waste vitrification that the effects of radiation on the density and mechanical properties of oxide glasses have been studied. The goal was to evaluate how radiation could affect fracturing of borosilicate glasses subjected to mechanical stresses through measurements of density, hardness, Young modulus, and fracture toughness. Most researches have addressed the influence of alpha decay, which is the main cause of atomic displacements in glass structures under disposal conditions. They have in addition tried to evaluate the respective roles of alpha particles and heavy recoil nuclei through external irradiation with light and heavy ions but also through thermal-neutron irradiation [16, 17]. Fewer studies have addressed the effects of beta decay through electron irradiation [7, 30].

A decrease in hardness and Young modulus, along with an increase in fracture toughness, is always observed. The hardness changes under heavy-ion irradiations are very similar regardless of the glass complexity in borosilicate systems [31], which suggests that they are controlled by the response of the borosilicate network itself. As a function of the irradiation dose, they follow exponential laws with a saturation at deposited energies of 30 MGy and

3 GGy by nuclear and electronic collisions, respectively [32]. Whereas collisions with nuclei are, therefore, about 100 times more efficient than with electrons, the hardness changes induced by the former are approximately twice greater than by the latter at electronic stopping powers lower than 2 keV/nm.

In alpha decay, both nuclear and electronic collisions occur simultaneously through the slowdown of the α particle and the recoiling nucleus. From experiments made under a wide variety of irradiation conditions, it appears that the accumulation of nuclear damage controls the hardness–dose relationship in oxide glasses subjected to alpha decay accumulation [17]. But the picture has been somewhat clarified by dual-beam irradiation experiments made with He and Au ions to study in more detail the synergistic effects of α particles and recoil nuclei on the extent of damage [32]. From sequential and simultaneous ion irradiation, the conclusion drawn is that the electronic energy losses of the α particles induce partial repair of the damage generated by the heavy ions. In other words, the state of the damaged glass is controlled by the mutual interactions between α particles and recoil nuclei.

In microscopic terms, a complementary picture has been brought by molecular dynamics simulations of the indentation of a rapidly quenched disordered sodium borosilicate glass [33]. Under these conditions, the increase of the free volume and the decrease of the polymerization index are the main factors accounting for the hardness decrease of the glass.

8 Mitigation of Radiation Effects

Hydrogen plays a key role in the glass radiation response as it easily interacts with point defects. Hydrogen effects on optical glasses have been thoroughly studied [34] because H_2 loading of germanosilicate optical fibers greatly increases their photosensitivity to ultraviolet laser light, opening the way to the manufacturing of Fiber Bragg gratings. Under irradiation, a glass containing H_2 molecules usually presents a lower radiation sensitivity because hydrogen passivates most of the radiation-induced defects such as the SiE' or non-bridging hole centers [5]. However, it should be considered that the H_2 loading also presents adverse effects such as an increase of the linear attenuation at telecom wavelengths. Furthermore, this hardening technique is difficult to implement for fiber-based systems having to operate during long periods such as in space mission or nuclear industry as the gas easily diffuses out the fiber. Today, no optical glass or optical fiber can be considered as radiation hardened for all harsh environments, even if solutions exist for most of the currently targeted applications [9].

For lenses, most studies have been devoted to glass hardening under conditions relevant to space and those encountered at CERN, which means moderate doses typically not exceeding 100 kGy. In this case, co-doping of glasses with cerium strongly reduces the RIA levels [27], thanks to the incorporation of this element in the silica network as Ce^{3+} or Ce^{4+} ions: as already noted, upon irradiation, Ce^{3+} ions trap the released holes to form $(Ce^{3+})^+$ centers, which inhibit the formation of other trapped hole centers, whereas Ce^{4+} ions trap electrons, which reduces the formation of all centers due to trapped electrons. The relative abundances of both species strongly depend on the redox conditions of manufacturing process. These mechanisms may have a very positive effect on the levels of RIA in the visible so that radiation-hardened glasses are commercially available, with a transmittance edge shifted to longer wavelengths by the absorption of Ce^{3+} and Ce^{4+} ions around 320 and 260 nm. These cover a sufficient part of the Abbe diagram (Chapter 6.1) to make the design of performance optical systems possible for low-to-moderate dose environments. These Ce-bearing glasses are prone to dielectric breakdown, however, so that specific mitigation techniques, such as the addition of protective conductive layers, have to be applied to reduce this risk.

With Ce-co-doping, the radiation sensitivity of silica-based optical fibers has been reduced enough to open the way for a new generation of radiation-tolerant fiber lasers and amplifiers for the most challenging space missions [9]. Finally, Ce-doped silica-based fibers serve as very efficient dosimeters because the luminescence

intensity of Ce^{3+} ions at around 460 nm depends linearly on the dose rate. If the irradiation duration is known, the dose can then be calculated precisely.

Another approach might rely on the mixed alkali effect (Chapter 4.6) to slow down diffusion through mixing of alkalis in the glass composition [35]. In a series of five borosilicate glasses, the structural modifications of the glass network induced by electron irradiation are reduced by a slowdown of the migration of alkali charge-compensating cations for fourfold coordinated B^{3+} in mixed Na, K samples whereas the motion of modifier ions is reduced in Na, Li samples. In this way, the mixed alkali effect also affects boron speciation, i.e. BO_3/BO_4 ratios and, thus, the polymerization index. In addition, it can also act positively by limiting the concentration of point defects when both alkali ions are introduced in equal part in the glass.

Finally, the fictive temperature T_f may also be a parameter relevant to improve the radiation resistance of the glass. In silica, the density increases with T_f via a higher proportion of three- and four-membered rings, which yield a more strained structure. Correlatively, the concentrations of the SiE' , non-bridging oxygen hole center (NBOHC), and self-trapped hole (STH) point defects (Figure 3) increase [36]. Because the E' center and STH point defect contribute the most to optical absorption spectra, monitoring the fictive temperature can be beneficial to decrease the RIA of the fiber and, thus, to optimize its radiation hardness.

9 Perspectives

Even though much knowledge has been acquired in the last 50 years about radiation effects on glasses, several challenges remain to be overcome. First, the contribution of multiscale modeling must be increased, thanks to the development of new simulation tools and to advances in high-performance computing. It will become possible to consider more complex glass structures, to increase the size of the simulation cell, and to deal with the role of impurities so as to reproduce changes in local- to medium-range order. Second, more highly functionalized glasses or optical fibers (e.g. doped sol-gel materials [Chapter 8.2], doping with nanoparticles) will be developed to address new needs in terms of performance in sensing, medicine, or energy sectors. Those new glasses may be used in radiation environment for multiparameter sensing or for dosimetry in the future after having demonstrated their potential in civil applications. Third, new radiation environments will have to be considered either in space or on Earth in facilities devoted to research on nuclear fusion (LMJ, ITER, or DEMO) for which the vulnerability of

glasses and optical fibers will have to be evaluated and radiation hardening studies conducted to ensure their operability. Some of the technical challenges will not be easy to sustain; for instance, the combined radiation and temperature constraints associated with the space missions to the moons of Jupiter or with the in-core monitoring of the next generation of nuclear reactors with temperatures ranging up to 1000 °C. For a given glass and harsh environment, the radiation response will also be driven by the chosen operation profile for the application: operating wavelength(s), the injected light power level, and pre- or posttreatments [9].

Amorphous Ices

Robert F. Tournier

Institute of Engineering, Université Grenoble Alpes, CNRS, Grenoble INP, Institut Néel, Grenoble, France

1 Introduction

Despite its chemical simplicity, water is one of the most complex substances known as exemplified by unusual properties such as a density maximum near 4 °C, a negative volume of melting, and, thus, freezing temperatures decreasing with increasing pressure. As for the solid phases of water, they are also remarkable in view of the existence of at least 15 ice polymorphs [1]. These original aspects of water largely originate in a contrast between strongly covalent intramolecular H–O bonds and weaker intermolecular bonds between the lone electron pair of the oxygen of a given molecule and the hydrogens of two other molecules. Understanding how a complex interplay of these bonding features results in the unusual properties of H₂O is of a more than purely academic interest because water typically constitutes 80 wt % of living organism and covers 70 % of the Earth's surface. With its vapor in the atmosphere and the large ice caps found around the poles, water is in fact the only important substance naturally occurring so close to its triple point.

The picture of water phases and properties is still more complex because it must also include amorphous ices and their own peculiarities. Although liquid water does not vitrify upon continuous cooling, an amorphous form of ice was first obtained in 1935 by vapor deposition on a copper surface kept below –110 °C [2]. It has been termed low-density amorphous (LDA) ice in view of its room-pressure density of 0.94 g/cm³, which is close to the 0.92 g/cm³ of ice I. This amorphous ice may form in the coldest regions of the Earth's atmosphere, such as the summer polar mesosphere, and might be the most

common form of water in the whole universe either as vapor-deposited thin films onto solid surfaces or as confined in nanometric pores of interstellar matter [3].

Half a century after the synthesis of LDA, another amorphous water phase was obtained below 140 K through uniaxial compression of either hexagonal ice or of the LDA phase at pressures higher than 1.6 GPa (Figure 1) or 0.5 GPa, respectively (Chapter 3.10, [4]). Because of its room-pressure density of 1.17 g/cm³ at 77 K, this phase has been called high-density amorphous (HDA) ice (Figure 1). Further work then showed that HDA ice transforms itself into a third amorphous phase if brought between 1 and 2 GPa at 160 K [5]. Its room-pressure density of 1.26 g/cm³ at 77 K has led this third phase to be discovered at 125 K under 0.95 GPa and termed very high-density amorphous (VHDA) ice [6].

Probably, the most important consequence of these unexpected discoveries was to raise the issue of *polyamorphism*, i.e. of first-order transitions between amorphous phases, and, in turn, of the relevance of this concept to oxide and other glass-forming systems. Because this important topic is dealt with in Chapter 3.9, the focus will be out here to the original amorphous ices and to the way in which their mutual relationships can be understood thermodynamically.

For this purpose, the origin of ice polyamorphism will be rooted in a first-order phase transition between two distinct liquid phases [7], which nucleates homogeneously at different temperatures upon cooling [8]. After a review of the synthesis of these phases and of their thermochemical properties, a simple thermodynamic model will be set up to account for their coexistence curve in the *P,T* plane. The structural significance of these results and their extension to glass-forming liquids, in general, will then be pointed out, attention being in particular paid to glacial phases and ultrastable glasses whose existence is related to polyamorphism. Both have much lower

enthalpies than glasses obtained by melt cooling because the former result from isothermal annealing above T_g [9] and the latter are currently produced by vapor deposition below T_g [10]. Finally, a comparison will be made between H_2O and SiO_2 because of their structural similarities that have long been noticed [11].

Acronyms

HDA	high-density amorphous

VHDA	very high-density amorphous
VHDL	very high-density liquid
VFT	Vogel–Fulcher–Tammann

2 Ice Phase Transitions

2.1 Calorimetric Observations

All other things being equal, the probability of forming a crystal nucleus in a supercooled liquid is proportional to the size of the sample. For water, the highest degrees of supercooling of 40 K have thus been achieved for capillary samples. Upon cooling, the heat capacity of these samples strongly increases down to 235 K before crystallization takes place and prevents the glass transition from being

Figure 2 Low-temperature heat capacity of H_2O phases measured upon heating: hexagonal ice, supercooled liquid, and low-density amorphous ice undergoing a glass transition at 133.6 K [14]. *Source:* Reproduced with permission and adapted from [8], © Elsevier.

observed as a rapid C_p decrease [12, 13]. In contrast (Figure 2), a C_p increase typical of a glass transition was observed in 1968 at 133 K upon heating of the LDA ice before its onset of crystallization [14]. As characterized by a C_p rise of more than 35 J/K/mol, this glass transition near 134 K is followed by a sharp exothermic crystallization peak of 1.64 kJ/mol. Interestingly, the C_p peak of the supercooled liquid almost matches theoretically evaluated values [8], whereas the heat capacities of the LDA, hexagonal, and cubic ices are nearly the same below 134 K as may be expected from their purely vibrational nature.

Other relevant measurements have been made on H_2O phases enclosed into nanopores, but the contribution of interfacial water must then be removed as done for ice and emulsified water from the results obtained for pores of variable diameters [15, 16]. In 3 nm pores (Figures 3 and 4), water supercools readily and shows not only a C_p peak at 228 K [15] but also two apparent glass transitions at around 135 and 174 K [16]. In the absence of latent heat, a first-order transition at 228 K was not

clearly established, but the strong C_p peak of 112 J/K/mol at 227 K is suggestive of its existence. Such a phase transformation is indeed predicted at around 227 K by a two-state model [13, 17, 18], which also accounts well for the heat capacity of supercooled water measured above 235 K (Figure 5).

Together with the two glass transitions, the onset of ice crystallization at 235 and 135 K points to the existence of two distinct supercooled liquids of different densities between which there is a transition at around $T_{LL} = 228$ K at room pressure. This point belongs to a first-order transition curve $T_{LL}(P)$ in the P, T plane that terminates at a critical point [13, 17, 18]. This curve could thus delineate the stability limits of two supramolecular arrangements of hydrogen bonds in water and, also, induce at the same time a transformation from a fragile to a strong liquid (Chapter 3.8) as suggested in 1999

[19]. But its determination is made difficult by the fact that it is located within the first crystallization zone.

2.2 Phase and Volume Observations

As already noted (Figure 1), hexagonal ice transforms under pressure to the HDA phase at 77 K through a first-order transition [4]. In turn, HDA ice transforms at room pressure into the LDA phase upon isothermal annealing with a volume discontinuity at 116 K of about $0.12 \text{ cm}^3/\text{g}$ (Figure 6) and a volume change of about $0.3 \text{ cm}^3/\text{g}$ between 100 and 116 K [5]. The HDA–LDA ice transition must actually be viewed also as a univariant equilibrium curve in the P, T plane, which may be determined from the volume discontinuities observed as a function of both parameters (Figure 7). Interestingly, this volume change remains basically constant with a value of about $0.2 \text{ cm}^3/\text{g}$ [7], which is smaller than the aforementioned $0.3 \text{ cm}^3/\text{g}$.

Despite their density differences, LDA and HDA ices have similar X-ray diffraction patterns typical of amorphous phases with the expected shift toward shorter interatomic distances in the latter phase as compared with the former (Figure 8) [20]. Interestingly, their formation at around 0.45 and 0.95 GPa, respectively, depends on the compression rate in isothermal experiments performed at 125 K (Figure 9). The excess density at 0.95 GPa is quenched after decompression and leads to an additional volume reduction of $0.3 - 0.2 = 0.1 \text{ cm}^3/\text{g}$. The associated excess enthalpy relaxes and decreases with temperature until the LDA phase enthalpy is reached.

The density of supercooled water above 200 K has been calculated as a function of temperature and pressure with another two-liquid state model. The line of maximum density and that of a constant low-density water fraction

Figure 7 Volume changes as a function of pressure and temperature for the transition between the high- and low-density amorphous ices under nominal pressure of 0.55, 0.45, 0.38, and 0.32 GPa at 77, 100, 121, and 135 K respectively. Liquid water under 1.2 GPa at zero pressure also represented versus temperature. of about 0.12 have also been determined. The existence of a critical point at 227 K at 0.018 GPa is still proposed because of a very strong temperature dependence of the density variation at low pressures [13]. Finally, a minimum of the isothermal compressibility is observed at

Figure 9 Effect of the compression rate on pressure–density curves for isothermal compression of low-density amorphous ice at 125 K. *Source:* Reprinted with permission from [6], © APS.

318 K [21, 22], which is also accounted for by a two-liquid model [17].

3 Predictions of Glass–Glass and Liquid–Liquid Transitions

3.1 Preliminary Remarks

The starting point of the present thermodynamic analysis of amorphous ices in terms of two initial liquid phases is classical nucleation theory [23] as complemented for each liquid by an additional enthalpy term to predict the

existence of two distinct homogeneous nucleation temperatures T_{n-} and T_{n+} [8, 24]. The nuclei are superclusters, instead of nanocrystals, because these transformations take place in liquids and give rise to usual or ultrastable glasses or glacial phases even to new liquid phases.

Below the melting temperature of ice, T_m , an ordered liquid forms at the lower T_{n-} , i.e. in the no man's land, so it is not easily observed. Above T_m , the higher T_{n+} would signal the onset of superheating as characterized by the disappearance of liquid ordering. For pure liquid elements, one predicts with this model superheating temperatures T_{n+} of $1.198 T_m$ [24, 25] and a Lindemann constant of 0.103. As is well known, Lindemann criterion states that melting occurs when the average relative variations of atomic spacings ($\Delta d/d$) become with increasing temperatures higher than a threshold value, which can be determined from the additional enthalpy term at T_m [26].

The two liquids 1 and 2 have different homogeneous nucleation temperatures, namely, the higher $T_1 = T_n$ and the lower $T_2 = T_g$. The transition at T_g is associated with the reversible enthalpy change from liquid 1 to 2 and by the formation of a glass phase composed of percolating and interpenetrating critical superclusters of the same size in the two ordered liquids whose enthalpies are equal at $T_2 = T_g$.

The glass–glass and liquid–liquid transformations of water under pressure and their latent heats have been predicted [8] from only $T_g \cong 136.6$ K [27], the enthalpy of fusion ($\Delta H_m = 6000$ J/mol), the room-pressure melting temperature of ice ($T_m = 273.1$ K), and the temperature of the compressibility minimum (≈ 318 K) [21, 22]. The transition at T_{LL} is first-order despite the smallness or even the lack of enthalpy discontinuity all along the line $T_{LL}(P)$, which represents a temperature-induced transition from strong to fragile liquid. The high endothermic latent heat expected upon heating is not observed, because it is compensated by the exothermic peak associated with a transformation at 228 K into an ordered liquid called phase 3, which does vitrify below T_g .

Liquids 1 and 2 are fragile above T_{LL} and strong below. They have different homogeneous nucleation temperatures T_1 and $T_2 = T_g$. The glass transition temperature $T_2 = T_g$ of the fragile liquid is lower than T_{LL} but cannot be attained by cooling. As a rule, a strong liquid indeed undergoes a glass transition at the temperature at which the enthalpy difference between the two liquids vanishes, which is higher than that of the fragile liquid.

3.2 Nucleation Temperatures of Ordered Liquid 1 and Ordered Liquid 2

According to classical nucleation theory (Chapter 5.4), the nucleation rate J in a specimen of volume V after a time t is an exponential function of the Gibbs free energy barrier $\Delta G(T)$:

$$J = KVt \exp\left(-\frac{\Delta G}{k_B T}\right), \quad (1)$$

where k_B is Boltzmann constant. A nucleus grows spontaneous in a sample of volume V when J becomes equal to 1 after a time t , which occurs when $\Delta G(T)$ is equal to the critical energy barrier $\Delta G^*(T)$ at the temperature T . Homogeneous nucleation occurs at a temperature T_n in any sample volume V when $\ln K = \Delta G^*/k_B T$, with $\ln K \cong 90$. Liquid ordering induced by the nuclei is expected at this temperature but not observed because crystallization takes place before T_n can be reached. In this model, ΔG includes a negative volume contribution $4\pi R^3/3 \Delta H_m \theta/V_m$ defined by the formation enthalpy of the nucleus at the reduced temperature $\theta = (T - T_m)/T_m$ and a positive surface energy $4\pi R^2 \sigma_1$ depending on the radius R (Chapter 5.4). The critical radius obtained for $d(\Delta G)/dR = 0$ is

$$R_c = -\frac{2\sigma_1 V_m}{(\Delta H_m \theta)}, \quad (2)$$

where σ_1 is the surface energy and V_m is the molar volume. The critical radius is infinite at the temperature of a first-order transition, which is here the melting temperature T_m for $\theta = 0$. The critical energy barrier corresponding to R_c is also infinite for $\theta = 0$. There is no surviving nucleus above T_m because all entities are expected to undergo surface melting at T_m . This classical model neglects the Laplace pressure (ΔP) acting on the nucleus surface, which is proportional to the reciprocal of R . A complementary negative enthalpy $-4\pi R^3 \Delta H_m \varepsilon/3V_m$ must thus be added to ΔG , ε being a fraction of the melting enthalpy ΔH_m . Depending on θ^2 , this term complements the Taylor expansion of the enthalpy Eq. (9) of Chapter 5.4, the derivative $[d(\Delta G)/d\theta]_p$ at T_m remaining equal to the melting entropy $\Delta S_m = \Delta H_m/T_m$ as it must. The new nucleation equation leads to a critical radius proportional to $(1 + \varepsilon)(\theta - \varepsilon)^{-1}$. Large nuclei undergo surface melting, while others melt homogeneously at the reduced temperature $\theta = \varepsilon$ or at higher temperatures depending on whether their size is critical or much smaller than critical [28].

The number of molecules n in a critical nucleus, the two kinds of homogeneous nucleation temperatures θ_{n-} and θ_{n+} , and the thermally activated critical barrier ΔG^* can be calculated as follows [29]:

$$n = -\frac{8N_A k_B (1 + \varepsilon)^3 \ln K}{[27 \Delta S_m (\theta - \varepsilon)^3]}, \quad (3)$$

$$\theta_{n-} = \frac{(\varepsilon - 2)}{3}, \quad (4)$$

$$\theta_{n+} = \varepsilon, \quad (5)$$

$$\frac{\Delta G^*}{(k_B T)} = 12(1 + \varepsilon)^3 \ln \left(\frac{12(1 + \varepsilon)^3 \ln(K \cdot v \cdot t)}{[81(\theta - \varepsilon)^2 (1 + \theta)]} \right). \quad (6)$$

where N_A is the Avogadro number, v the sample volume, t the nucleation time, and ε the fraction of the molar ΔH_m denoted by ε_{ls} for a nucleus in liquid 1, by ε_{gs} for a nucleus in liquid 2, and by $\Delta\varepsilon_{lg} = \varepsilon_{ls} - \varepsilon_{gs}$ for a nucleus of glass phase 3. The parameters ΔH_m and T_m are assumed to be the same for all phases and not to depend on the nucleus radius R . Superclusters spontaneously form by homogeneous nucleation. They are known to have frequently an icosahedral structure (Chapter 2.5). The critical nuclei induce ordering of liquids 1 and 2 below their own homogeneous nucleation temperatures T_1 and T_2 defined by Eqs. (4) and (5). The two ordered liquids transform into glass phase 3 below $T_g = T_2$, which gives rise to various LLPT at new homogeneous nucleation temperatures T_{n+} , according to the thermal variations of $\Delta\varepsilon_{lg} = \varepsilon_{ls} - \varepsilon_{gs}$.

The critical radius and the thermally activated energy barrier are infinite at the homogeneous nucleation temperatures obtained for $\theta_{n+} = \varepsilon$ instead of $\theta = 0$ for the classical equation. Each liquid is ordered at $\theta = \theta_{n-}$. This order disappears upon superheating at $\theta_{n+} = \varepsilon > 0$ but can reappear upon supercooling at $\theta_{n+} = \varepsilon < 0$.

The coefficients ε_{ls} and ε_{gs} represent the critical values of $\varepsilon(\theta)$ in liquids 1 and 2 under pressure. They are related to the homogeneous nucleation temperatures θ_{n-} given by Eq. (4) for ordering formation in liquids 1 and 2 by

$$\varepsilon_{ls}(\theta) = \varepsilon_{ls0} \left(\frac{1 - \theta^2}{\theta_{0m}^2} \right) + \Pi_1, \quad (7)$$

$$\varepsilon_{ls}(\theta) = \varepsilon_{gs0} \left(\frac{1 - \theta^2}{\theta_{0g}^2} \right) + \Pi_2 + \Delta\varepsilon, \quad (8)$$

where P_0 is room pressure and $\Pi_1 = (P - P_0) V_{m1}/\Delta H_m$ and $\Pi_2 = (P - P_0) V_{m2}/\Delta H_m$ are the pressure contributions to the enthalpy coefficients ε_{ls} and ε_{gs} ; $\Delta\varepsilon$ is the latent heat of an existing first-order transition. The dependence of ε on θ^2 has been deduced from the maximum supercooling rate of 30 liquid elements [25]. The coefficients ε_{ls} and ε_{gs} are zero at the reduced temperatures θ_{0m} and θ_{0g} for $\Pi_1 = 0$ and $\Pi_2 = 0$, which correspond to the Vogel–Fulcher–Tammann (VFT) temperatures of the ordered liquids 1 and 2, respectively. The volume of the sample is minimum at the VFT temperature of liquid 1 because T_{0m} is larger than T_{0g} . Combining Eqs. (4) and (8), one obtains a quadratic Eq. (9) whose solutions θ_{n-} for liquid 2 is given by Eq. (10):

$$\varepsilon_{gs0} \theta_{0g}^{-2} \theta_{n-}^2 + 3\theta_{n-} + 2 - \varepsilon_{gs0} - \Pi_2 - \Delta\varepsilon = 0. \quad (9)$$

$$\theta_{n-} = \frac{\left(-3 \pm \left[9 - 4(2 - \varepsilon_{gs0} - \Delta\varepsilon - \Pi_2) \varepsilon_{gs0} / \theta_{0g}^2 \right]^{1/2} \right) \theta_{0g}^2}{(2\varepsilon_{gs0})}, \quad (10)$$

where θ_{n-} of ordered liquid 2 for the sign + is θ_2 .

Likewise, Eqs. (4) and (7) lead to a quadratic equation whose solutions θ_{n-} for liquid 1 are also given by Eq. (10) where $\Delta\varepsilon = 0$ and the subscripts $gs0$ and $0g$ are replaced by $ls0$ and $0m$ and Π_2 by Π_1 , respectively. The transition leading to ordered liquid 1 occurs upon cooling at θ_1 in the no man's land. It could have been first observed upon electrostatic levitation of a metallic melt [30]. The most important phase transition occurs at zero pressure at the homogeneous nucleation temperature θ_2 of ordered liquid 2: by mixing the ordered liquids 1 and 2, it leads to the formation of glass phase 3 characterized by the enthalpy coefficient $\Delta\varepsilon_{lg} = \varepsilon_{ls} - \varepsilon_{gs}$.

Liquid 1 is strong when T_{0m} is smaller than $T_m/3$ ($\theta_{0m} < -2/3$) and fragile when T_{0m} is higher than $T_m/3$ ($\theta_{0m} > -2/3$). These two families have different thermodynamic properties below T_g . In all strong liquids, the coefficients ε_{ls0} in Eq. (7) and ε_{gs0} in Eq. (8), calculated with $\Pi_2 = 0$, $\Pi_1 = 0$, and $\theta_g = \theta_2$, are determined from the known values of θ_2 , θ_{0g} , and θ_{0m} [29]; the glass transition then occurs at the temperature θ_g for which $\varepsilon_{ls} = \varepsilon_{gs}$. In the great majority of strong liquids, (θ_{0g}) is equal to -1 . For all strong glasses for which $\theta_{0m} = -2/3$ and $\theta_{0g} = -1$, the homogeneous nucleation temperatures of liquids 1 and 2 are equal to T_g at zero pressure. With a negative homogeneous nucleation temperature, liquid 1 cannot be ordered for $\theta_{0m} < -2/3$. Nevertheless, a liquid–glass transition still occurs in liquid 2 at a temperature called T_g , where $\Delta\varepsilon_{lg}$ is zero, and is associated with the enthalpy change from liquid 1 to 2. Phase 3 is ordered at $T < T_g$.

Alternatively, a liquid is *fragile* when there is a unique solution to each quadratic equation for Π_1 and $\Pi_2 = 0$. In all fragile liquids, the value of ε_{ls0} minimizing the additional enthalpy given in Eq. (11) is for $\Pi_1 = 0$ and $\theta_1 > \theta_g$:

$$\varepsilon_{ls}(\theta = 0) = \varepsilon_{ls0} + \Pi_1 = 1.5 \times \theta_1 + 2 + \Pi_1 = a \times \theta_g + 2 + \Pi_1, \quad (11)$$

where a is unity in many of them and the reduced temperature (θ_{0m}) respecting Eq. (12):

$$\theta_{0m}^2 = \frac{8}{9} \varepsilon_{ls0} - \frac{4}{9} \varepsilon_{ls0}^2. \quad (12)$$

The additional enthalpy of liquid 2 is minimized with the coefficient ε_{gs0} given by Eq. (13) for $\Pi_2 = 0$ and $\Delta\varepsilon = 0$ [29]:

$$\varepsilon_{gs}(\theta = 0) = \varepsilon_{gs0} + \Pi_2 = 1.5 \times \theta_g + 2 + \Pi_2 + \Delta\varepsilon \quad (13)$$

when Eq. (14) is respected:

$$\theta_{0g}^2 = \frac{8}{9} \varepsilon_{gs0} - \frac{4}{9} \varepsilon_{gs0}^2. \quad (14)$$

The glass transition θ_g of a fragile liquid now occurs at a temperature smaller than that for which $\varepsilon_{ls} = \varepsilon_{gs}$.

3.3 High-Pressure Homogeneous Nucleation of Glass Phase 3

Below θ_g , the difference between the enthalpy coefficient ($\Delta\epsilon_{lg}$) of liquids 1 and 2 given by Eq. (15) under pressure gives rise to the new glass phase 3 instead of ordered liquid 2:

$$\Delta\epsilon_{lg}(\theta) = \epsilon_{ls} - \epsilon_{gs} = \epsilon_{ls0} - \epsilon_{gs0} + \Delta\epsilon + \Pi_1 - \Pi_2 - \theta^2 \left(\epsilon_{ls0}/\theta_{0m}^2 - \epsilon_{gs0}/\theta_{0g}^2 \right), \quad (15)$$

where $\Delta\epsilon$ is here a latent heat or an excess enthalpy frozen in upon quenching. The difference $\Delta\Pi = \Pi_1 - \Pi_2 = \delta V P / \Delta H_m$ is proportional to the volume change δV and to the pressure P at the transition temperature. Then $\Delta\Pi$ is zero for $\delta V = 0$, and T_g remains unchanged under pressure in the absence of latent heat. For a first-order transition, T_g is given by Eq. (10) in which $\Delta\epsilon$ is the latent heat and $\Pi_2 = 0$.

When heated above the glass transition θ_g at zero pressure, the glass phase 3 transforms into the ordered liquid phase 3, which can superheat above T_g and T_m . This liquid “melts” upon heating of the critical superclusters at the reduced temperature $\theta_{n+} > 0$ given by Eq. (3), but it can nucleate again at much lower temperatures from smaller superclusters not melted by overheating ($\theta_{n+} < 0$). In agreement with Eq. (5), one calculates $\theta_{n+} = \Delta\epsilon_{lg}$ with $\Delta\epsilon = 0$ and $(\Pi_1 - \Pi_2) = 0$ from Eq. (15). The nucleation temperature ($\theta_{n+} < 0$) depends on the overheating rate of liquids above T_m and is expected to vanish when all superclusters surviving above T_m have melted.

The melting enthalpy of phase 3 given by Eq. (15) for $\theta = 0$ is $\Delta\epsilon_{lg0} = \epsilon_{ls0} - \epsilon_{gs0}$, which reveals the presence of an underlying first-order transition without latent heat at a temperature T_{K2} at which $\Delta\epsilon_{lg}(\theta)$ and $-\Delta\epsilon_{lg0}$ are equal [24, 31]. The reason why T_{K2} cannot be attained in supercooled water is simply that it is lower than the Kauzmann temperature. The excess enthalpy coefficient at T_m is $-\Delta\epsilon_{lg}(T_K)$ instead of $\Delta\epsilon_{lg0}$.

3.4 Transformation of Phase 3 Under Pressure into a Lower-Enthalpy Glass

The thermally activated energy barrier is defined by Eq. (16) for the transformation of phase 3 [29]:

$$\Delta G^*/(k_B T) = 12(1 + \Delta\epsilon_{lg})^3 \frac{\text{Ln}(K, \nu, t)}{[81(1 + \theta)\Delta\epsilon_{lg}^2]}. \quad (16)$$

The enthalpy of phase 3 varies with P as shown in Eq. (15) and causes $\Delta\epsilon_{lg}$ to vanish before the transformation at the temperature θ_{sg} that depends on $(\Delta\Pi, \Pi_1 - \Pi_2)$. The

enthalpy difference between the HDA and LDA phases after the first-order transition is limited for all pressures by the maximum enthalpy change $\Delta\epsilon_{lg}(\theta_{0m})$ obtained at the VFT temperature $T_{0m} = T_m/3$ of liquid 1 with T_m decreasing under pressure.

The reduced transformation temperature θ_{sg} depends on pressure, because of its initial contribution ($\Delta\Pi_1 = \Pi_1 - \Pi_2$) to Eq. (15), and also on enthalpy at the onset of the first-order transition:

$$\theta_{sg} = - \left[(\epsilon_{ls0} - \epsilon_{gs0} + \Delta E + \Delta\epsilon + \Delta\Pi_1)^{1/2} \left(\frac{\epsilon_{ls0}}{\theta_{0m}^2} - \frac{\epsilon_{gs0}}{\theta_{0g}^2} \right)^{-1/2} \right]. \quad (17)$$

Here a new coefficient ΔE is added because the underlying first-order transition at $T_{sg} = T_K$ fixes the minimum value of $\Delta\epsilon_{lg}(\theta)$ at the Kauzmann temperature instead of $\Delta\epsilon_{lg0}$ at a lower temperatures [24, 31]. This coefficient ΔE affects two temperatures T_{sg} . First, for the HDA phase the parameter $\Delta\epsilon_{lg}$ of Eq. (15) is zero at its T_g calculated with Eq. (10) under the Laplace pressure of a confined space, i.e. $\Pi_1 - \Pi_2 = 0$, $T_m = 273.14$ K, and $\Delta\epsilon = \Delta\epsilon_{lg}(T_{0m})$. Upon annealing at this temperature, this transition to a glacial phase could take place under Laplace pressure [24]. The value of ΔE in Eq. (17) is then determined for $\theta_{sg} = \theta_g$, $\Delta\Pi = 0$, and $\Delta\epsilon = 0$ at the onset of the transition. Second, the underlying first-order transition occurs here at the Kauzmann temperature T_K when $\Delta\epsilon_{lg}$ attains its minimum value $\Delta\epsilon_{lg}(T_K)$. Because there is no entropy left at T_K , this underlying transition also occurs without latent heat, i.e. for $\Delta\epsilon_{lg} = 0$ in Eq. (15), and is accompanied by an enthalpy change $\Delta\epsilon_{lg0} + \Delta E = 2 \Delta\epsilon_{lg}(T_K)$ that leads to an ultrastable glass phase with $\Delta\Pi = -\Delta\epsilon_{lg}(T_K)$ and $\Delta\epsilon = 0$ when $T_{sg} = T_K$. Only the latent heat $\Delta\epsilon_{lg}(T_K)$ of the ultrastable phase can then be recovered at T_g by relaxation because the second part $\Delta\epsilon_{lg}(T_{K2})$ remains an excess enthalpy up to T_m . The Kauzmann temperature of supercooled water is determined from $\Delta\epsilon_{lg0} + \Delta E = 2 \Delta\epsilon_{lg}(T_K)$.

4 Numerical Applications to Water

4.1 Heat Capacity Below T_g at Zero Pressure and Kauzmann Temperature

The reduced temperatures θ_{0g} and θ_{0m} of the strong liquids are -1 and $-2/3$, respectively, because the VFT temperatures are assumed to be 0 K below T_g for liquid 2 and $T_m/3$ for liquid 1. From $T_g = 136.2$ K [27] and $\theta_g = -0.50128$, one calculates ϵ_{ls} , ϵ_{gs} , and their difference $\Delta\epsilon_{lg} = \epsilon_{ls} - \epsilon_{gs}$ with Eqs. (9) and (15) and the coefficients of Table 1.

The specific heat of the supercooled phase 3 is $\Delta H_m d(\Delta\epsilon_{lg})/dT$ (Figure 2). Without imposing any entropy

constraint induced by the Kauzmann temperature, one finds that the minimum enthalpy coefficient of phase 3 is -0.36816 for $\epsilon_{ls} = 0$ at $\theta = \theta_{0m} = -2/3$ (Figure 10) and that the enthalpy available below T_g is 1640 J/mol from the crystallization enthalpy around T_g [14]. The minimum enthalpy cannot be attained because the crystal enthalpy difference of 1640 J/mol is much smaller than 2209 J/mol (i.e. 0.36816 times 6000). Between 116.7 and 228 K, the entropy change calculated from the theoretical C_p is already $\Delta S_m = 21.967$ J/K mol. The Kauzmann temperature is higher than the previous evaluation of 115.5 K [8], with a value $T_K = 120.4$ K (Section 4.3) associated with a crystallization enthalpy of 0.23364 $\Delta H_m = 1402$ J/mol.

Upon isothermal relaxation from VHDA to LDA ice (Figure 6), the volume changes by about $0.12 \text{ cm}^3/\text{g}$ at 116 K, when $\Delta\epsilon_{lg}$ is zero as predicted by Eq. (17) with an excess enthalpy $\Delta\epsilon = -\Delta\epsilon_{lg} = 0.15188$ and $\Delta\Pi = 0$,

Figure 10 Enthalpy coefficients of supercooled water below T_g . Line 1: relaxation of the enthalpy coefficient $\Delta\epsilon_{lg}$ of phase 3 from VHDA to LDA (corresponding to the volume relaxation in Figure 6). Line 2: $\Delta\epsilon_{lg} = 0$; glass phase 3. Line 3: $\Delta\epsilon_{lg} = -0.11682$; fully relaxed glass phase 3. Line 4: $\Delta\epsilon_{lg} = -0.23364$, ultrastable glass phase 3 down to $T_K = 119.7$ K. Line 5: phase 3 in the absence of the glass transition. For $T = T_{0m} = 91.05$ K, $\Delta\epsilon_{lg} = -0.36816$.

leading to a change in the enthalpy coefficient of 0.23364. In a plot of $\Delta\epsilon_{lg}$ against T (Figure 10, where the axis $\Delta\epsilon_{lg}$ is reversed), this process represented by line 1 leads to the formation of an ultrastable LDA phase 3 on line 4. By comparison, the glass phase is represented by line 2 for $\Delta\epsilon_{lg} = 0$ and the fully relaxed glass by line 3. Sharp transitions at temperatures T_{sg} (where $\Delta\epsilon_{lg} = 0$) toward glasses of lower enthalpy are indeed predicted by Eq. (17) when an excess enthalpy is frozen in upon quenching [24].

The enthalpy coefficient of the fully relaxed glass phase cannot be smaller than its value (-0.11682) at the Kauzmann temperature T_K , whereas that of the ultrastable phase 3 cannot be smaller than -0.23364 . An underlying first-order transition without latent heat occurs at T_K as predicted by theoretical work [31]. In addition, there is no more enthalpy available at T_K for a first-order transition accompanying the formation of the ultrastable phase 3.

4.2 Heat Capacity of Confined Water and the Glass Transition at $T_g = 177.5$ K

According to Young–Laplace equation, $\Delta P = 2\gamma/R = 0.11$ (2) GPa for $R = 1.5$ nm and a surface tension γ of 0.085 (5) J/m² at 227.5 K as extrapolated above 250 K [32]. For $R = 0.55$ nm, ΔP is about 0.30 (4) GPa.

A C_p bump of about 112 J/K mol is observed around 228 K for 3 nm pores (Figure 3). This value is used to fix $a = 0.85$ in Eq. (11) and reproduce the 37.9 J/K mol C_p increase of the fragile phase 3 from T_m to 230.35 K (cf. Section 4.5). Although T_{LL} does not depend on Laplace pressure and T_m still is 273.1 K, the excess

enthalpy $\Delta\epsilon$ relaxes for water confined into 3 nm pores submitted to Laplace pressure (Figure 4). Two apparent transitions are found: in the first, the initial $\Delta\epsilon$ disappears around $T_g = 136$ K, whereas the new $\Delta\epsilon$ does so near 174 K under Laplace pressure. In all HDA ices under critical pressure, T_g is equal to $0.65 T_m$. The same applies to confined water with a T_m of 273.1 K (Figure 4).

4.3 First-Order LDA–HDA Ice Transition Under Pressure

With the parameters of Table 2, the LDA–HDA transition can also be analyzed in terms of an enthalpy excess change occurring at $\theta = \theta_{sg}$ under pressure (Figure 11). The LDA phase 3 has an effective excess $\Delta\epsilon_{eff} = \Delta E + \Delta\Pi_1$ in Eq. 15 ($\Delta\epsilon = 0$) before the occurrence of the transition. This first-order transformation is such that the total enthalpy increase at equilibrium cannot be larger than the maximum enthalpy difference $0.36816 \Delta H_m$ (produced at the VFT temperature $\theta_{0m} = -2/3$) to escape from crystallization. The HDA phase has an enthalpy difference ($\Delta\Pi_2$) with the LDA phase at the temperature T_{sg} after transformation. In all transitions $|\Delta\Pi_2|$ is equal to this maximum value obtained under a pressure of 0.55 GPa: $P \Delta V_2 / \Delta H_m = 0.36816$ with $P = 0.55$ GPa and $\Delta V_2 = -0.22 \times 10^{-6}$ cm³/g.

As discussed in Section 3.4, the temperature $T_{sg} = T_g = 177.5$ K is used to determine ΔE because $\Delta\epsilon_{lg}$ and $\Delta\Pi_1$ are zero at the onset of this transition. With Eq. (17), one then finds $\Delta E = -0.24529$ (Table 2). The Kauzmann temperature is 120.4 K for $\Delta\epsilon_{lg} = (\Delta\epsilon_{lg0} + \Delta E)/2 = 0.11682$, $\Delta\epsilon$, and $\Delta\Pi = (\Pi_1 - \Pi_2) = 0$ in Eq. (15).

Table 2 First-order glass-to-glass transitions under various pressures.

1	P (GPa)	0.55	0.45	0.38	0.32	0
2	T_{sg} (K)	77	100	121	133.3	177.5

1. Pressure (P); $P = 0$ includes Laplace pressure. 2. First-order transition temperature under pressure P . 3. Pressure-dependent melting temperature. 4. ΔE , enthalpy coefficient excess at T_{sg} . 5. ($\Delta\Pi_1 = P \times \delta V_1 / \Delta H_m$), the change of the enthalpy coefficient associated with the volume difference δV_1 between liquid and glass before the transformation from LDA to HDA under pressure (P). 6. ($\Delta\epsilon_{eff} = \Delta\Pi_1 + \Delta E$); 7. $\theta_{sg} = (T_{sg} - T_m) / T_m$ calculated with Eq. 17. 8. ($\Delta\Pi_2 = P \times \delta V_2 / \Delta H_m$), change of the enthalpy coefficient associated with the volume difference induced by the first-order transition under pressure. 9. ($\theta_g = (T_g - T_m) / T_m$), reduced glass transition temperature of HDA under pressure.

Figure 11 Enthalpy coefficients vs. pressure (P) and sharp enthalpy coefficient changes ($\Delta\epsilon_{lg}$) at $\theta = \theta_{sg}$: HDA line represented by ($\Delta\epsilon_{eff} + 0.36816$) versus P (GPa). Enthalpy coefficient changing ($\Delta\epsilon_{lg} = -0.36816 = \Delta P_2$) on vertical lines. LDA line: calculated points of $\Delta\epsilon_{eff}$ corresponding to Mishima's measurements reproduced in Figure 7 at 77 K and 0.55, 0.45, 0.38, and 0.32 GPa.

In Table 1, $\Delta\epsilon_{eff}$ is calculated with Eq. (17) and $\Delta\epsilon = 0$ at the reduced temperature θ_{sg} , whereas $\Delta\Pi_1$ is proportional to P with $\Delta E = -0.24529$. The melting temperature T_m under pressure is deduced from θ_{sg} and T_{sg} in agreement with the experimental values [33].

A transition at $T_g \cong 180$ K is observed in the heat capacity of all deposited thin films. It can be attributed to a thin layer in contact with the substrate because the latent heat of the first-order transition is very small compared with $0.36816 \Delta H_m = 2209$ J/mol [34].

4.4 VHDA Ice

Following the volume change assigned to the HDA–VHDA transformation observed at 125 K at $P \approx 0.95$ GPa (Figure 9), an additional volume reduction of 0.0855 [6] or $0.1 \text{ cm}^3/\text{g}$ (Figure 6) is observed after decompression at 77 K. In the strong liquid, this transition occurs above T_m when Eq. (3) is respected for $\theta_{n+} = 0.3034$ ($T_{n+} = 1.3034 T_m$) and is accompanied by an endothermic enthalpy of $0.3034 \Delta H_m = 1820$ J/mol. The theoretical volume change $\delta V = 0.3034 \Delta H_m / P = 18 \times 10^{-7} \text{ cm}^3/\text{mol}$ agrees with the experimental results (Figures 6 and 9). At 0.95 GPa, the melting temperature of ice Ih is $125/1.3034 = 96$ K, in agreement with Mishima's measurement [33]. This transformation at 125 K above T_m leads to a VHDL instead of a VHDA phase whose amorphous state is caused by the decompression upon increases of T_m . This first-order transition above T_m represents “melting” of the ordered liquid phase 3. Despite the predictions of Eq. (5), this phase does not nucleate at $\theta_{n+} = \Delta\epsilon_{lg} = -0.3034$ upon decompression because the excess enthalpy has not disappeared. All residual superclusters melt as T_m becomes much lower than 125 K above 1.4 GPa, whereas the lack of a transition induced by residual nuclei causes the additional volume

reduction of $0.1 \text{ cm}^3/\text{g}$ to be frozen in after decompression.

4.5 Fragile-to-Strong Liquid Transformation of Water at Room Pressure

To obtain a weakly endothermic effect upon heating and a glass transition temperature of 136.22 K ($\theta_g = -0.50128$), the temperature of the first-order fragile-to-strong liquid transition of water T_{LL} is taken here as 230.35 K ($\theta_{LL} = -0.15665$). The temperatures T_{Br-} and T_{Br+} (Table 1) are such that $\Delta\epsilon_{lg}$ is 0 in Eq. (16), with $\Delta\epsilon = 0$ and $\Pi_1 = \Pi_2 = 0$, and they cannot depend on P because of the lack of an initial volume difference. In the fragile state, the reduced temperatures $\theta_{LL} = \pm 0.15665$ (i.e. θ_{Br+} and θ_{Br-}) are symmetrical with respect to T_m (Figure 12). Whereas the transition from liquid 1 to liquid 2 is expected at T_{Br-} , there is a compressibility minimum of bulk water for $\Delta\epsilon_{lg} = 0$ above T_m at around 317 K because liquids 2 and 1 have the same enthalpy coefficient [21, 22]. The value $a = 0.85$ in Eq. (11) is used for the fragile liquid 1 and leads to $T_{om} = 169.7$ K, in good agreement with the VFT temperature 168.9 K [35]. The specific heat $d(\Delta\epsilon_{lg})/dT \Delta H_m$ of phase 3 at T_{LL} is taken as 37.6 J/K/mol in agreement with its variation between T_m and 227 K (Figure 3).

The enthalpy of liquid 1 strongly increases upon heating through T_{LL} , whereas that of phase 3 decreases (Figure 12). The two latent heats are nearly equal with opposite signs, their difference at T_{LL} being $1.4 \times 10^{-4} \Delta H_m = +0.84$ J/K mol. Glass phase 3 then transforms into an “ordered” liquid at T_g , which exists up to T_{LL} . A first-order transition without apparent latent heat is consistent with the C_p of confined water (Figure 2), which does not reveal highly critical variations at T_{LL} [15].

Figure 12 Enthalpy coefficients ϵ_{lg} , ϵ_{gs} , and $\Delta\epsilon_{lg}$ of liquid 1, liquid 2, and phase 3 (see Table 1), $\Pi = 0$. Strong liquid 1 below $\theta_{LL} = -0.15665$ and fragile liquid 1 above θ_{LL} . Characteristic temperatures: $T_{om} = 91.05$ K, $T_{K2} = T_K = 220.4$ K, $T_g = T_{Br-} = 136.22$ K, $T_{LL} = 230.35$ K, $T_{n+} = 248.47$ K, $T_m = 273.14$ K, $T_{n+} = 297.81$ K, $T_{Br+} = 315.93$ K. Source: Reproduced with permission and adapted from [8], © Elsevier.

Phase 3 contributes to the enthalpy change at T_{LL} only when it is ordered after cooling of supercooled water below T_g or $T_{n+} = 190.3$ K, the existence of this transition depending on the rate at which residual water superclusters melt upon overheating.

Upon heating, the model predicts the appearance at T_{LL} of a new fragile and ordered phase 3 existing up to $T_{n+} = 297.8$ K – $\theta_{n+} = 0.09031$ with Eq. (5), which could reappear at 248.5 K after a very moderate overheating above 298 K. But crystallization has until now prevented these predicted supercooled and superheated phases 3 from being observed.

The excess $\Delta\epsilon_{lg0}$ of the fragile phase 3 given by Eq. (15) at $\theta = 0$ is 0.13527 instead of being exactly $\Delta\epsilon_{lg}(T_K) = 0.11682$. The parameters T_{LL} and a in Eq. (11) can be adjusted to obtain a strict equality. The existence of an underlying first-order transition without latent heat is confirmed.

4.6 The Phase Diagram of Water at $-0.175 \leq P \leq 0.176$ GPa

The reduced temperature θ_{LL} does not depend on P despite the proportionality relation $T_{LL} = 0.84335 T_m$. Without changing the values of θ_{LL} and θ_g , pressure simply induces a vertical translation of all points $\Delta\epsilon_{lg} = 0$ in Figure 12. The enthalpy coefficients of fragile liquids at T_{LL} cannot be higher than 2. Consequently, the first-order transition at T_{LL} exists up to a pressure $P \approx 0.176$ GPa corresponding to $\Pi_1 = \Pi_2 = 0.49003$ and a density $\rho = 1.08$ g/cm³. In the phase diagram of supercooled water (Figure 13), the homogeneous nucleation temperatures θ_2 and θ_1 of the strong liquids 2 and 1 are calculated as a function of Π_2 and Π_1 with Eq. (10) for $\Delta\epsilon = 0$: they are higher than the thermodynamic transition at $\theta = -0.50128$. The parameter Π_2 is 0.88363 at $T_{LL} = 230.35$ K. The homogeneous nucleation temperature θ_1 of the strong liquid 1 cannot become greater than zero after a first-order transition at T_{LL} . There is no strong-to-fragile transformation above $\Pi_1 = 0.8575$ and 227.8 K upon heating and no fragile-to-strong transformation above $\Pi_2 = 0.88363$ and $T_{LL} = 230.35$ K upon cooling. Water remains a strong liquid above θ_{LL} and $\Pi_2 = 0.88363$ ($0.31 < P < 0.55$ GPa) with its existing θ_2 despite the disappearance of θ_1 . The line $T_{LL}(P)$ has an upper limit set by $\Pi_1 = 0.49003$ ($P \approx 0.176$ GPa).

The C_p increase at zero pressure below T_m proves that the LLPT at T_{LL} is always present at lower pressures for $\Pi_1 = \Pi_2$ and disappears at the negative pressure $\Pi_1 = \Pi_2 = -0.49616$ when the latent heat vanishes. The value of ϵ_{ls} at θ_g is 0.49916 when pressure is not applied and cannot be negative under pressure. The lower limit represents the other end of the first-order transition line and confirms that the stability limit of phase 3 is $P \approx -0.149$

Figure 13 Phase diagram of supercooled water and strong liquids under pressure. Curves numbered from 1 to 3. 1, Reduced homogeneous nucleation temperature (θ_1) of strong liquid 1 vs. enthalpy coefficient Π induced by pressure P . 2, Reduced homogeneous nucleation temperature (θ_2) of strong liquid 2 vs. enthalpy coefficient Π induced by pressure P . 3, LLPT line separating the fragile liquid phase from the strong one at $\theta_{LL} = -0.15665$. Ends of the first-order transition line $T_{LL}(\Pi)$: $\Pi = -0.49616$, $P \approx -0.157$ GPa; $\Pi = 0.49003$, $P \approx 0.176$ GPa. Source: Reproduced with permission and adapted from [8], © Elsevier.

GPa assuming a density ρ of 0.9 g/cm³. This last critical point (Figure 13) is close to the maximum density evaluated at a negative pressure of 0.140 GPa [36], which contradicts previous conclusions [8] because pressure also acts on fragile liquid states. Above 0.31 GPa, the phase diagram is deeply modified by first-order transitions at $T_g = 0.65 T_m$.

In the P, T representation of the first-order transitions of supercooled water (Figure 14), the equilibrium line $P(T_{LL})$ is calculated with $T_{LL} = 0.84335 T_m$. The density is roughly estimated to be 0.9 g/cm³ for all negative pressures, and T_m obeys the Clausius–Clapeyron relation $dP/dT = -0.0134$ GPa/K. The transitions at T_{LL} and T_{sg} cannot take place at the same pressure: T_{LL} exists only for $-0.149 < P < 0.176$ GPa, and T_{sg} for $0.31 < P < 0.55$ GPa,

Figure 14 Diagram P, T of first-order transitions in supercooled water. T_{sg} : transformation temperatures LDA–HDA for $0.31 < P < 0.55$ GPa. T_{LL} : liquid–liquid phase transition for $-0.149 < P < 0.176$ GPa; for $P > 0.176$ GPa, disappearance of T_{LL} ; for $P = 0.057$ GPa and $P = 0.107$, the homogeneous nucleation temperatures are equal to T_m ; for $P < -0.149$, disappearance of strong phase 3.

Table 3 Dependence of the critical number n of supercluster atoms at T_g on melting entropy as calculated from Eq. (3).^a

Number	1	2	3	4	5	6
Materials	Pure metals	H ₂ O	GeO ₂	BeF ₂	SiO ₂	NaAlSi ₃ O ₈
ΔS_m (J/g.atom K)	9	7.33	4	19.3	1.49	3.65
n	83	102	187	390	505	211
θ_g	-0.6223	-0.5	-0.396	-0.285	-0.262	-0.2018
ϵ_{gs0}	0.217	0.6667	0.963	1.2462	1.3035	1.4538

^a $\epsilon_{gs0} = (3\theta_g + 2)/(1 - \theta_g^2)$ from Eq. (9) with $\Delta\epsilon = 0$ and experimental values of $\theta_g = (T_g - T_m)/T_m = \theta_{n-}$.

and T_{LL} is nonexistent for $P > 0.176$ when the enthalpy coefficients of fragile liquids at 230 K are greater than 2.

5 Supercluster Formation at the Glass Transition of Strong Liquids

Among strong and fragile liquids, d-mannitol [C₆H₁₄O₆] (Chapter 11), *n*-butanol [C₄H₁₀O], and triphenyl phosphite [P(OC₆H₅)₃] are receiving particular attention [24]. The enthalpy constraint for the formation of a glacial phase by isothermal annealing in these liquids is respected even though the relevant enthalpy difference then is $\Delta\epsilon_{lg}(\theta_{om}) - \Delta\epsilon_{lg0}$ instead of $\Delta\epsilon_{lg}(\theta_{om})$ only for LDA and HDA. A glass phase 3 having a frozen-in entropy close or equal to that of crystals can exist beyond the first glacial phase as observed for the second such phase of *n*-butanol [24]. For the three liquids, the glacial phase results from first-order transitions of fragile or strong liquids 2 without changing the enthalpy of liquid 1 [24]. A deep first-order transition from fragile to strong liquid 1 does not exist, contrary to that experienced by water at $T_{LL} \cong 227\text{--}230$ K, which could be related to its proximity to the triple point [13, 17, 18].

Turning now to SiO₂, we note a first similarity with H₂O in that the low-pressure phases of both substances are described as open networks of either OH₄ or SiO₄ tetrahedra. In SiO₂ phases, the marked contrast between strong Si—O intratetrahedral and weak Si—O—Si intertetrahedral bonds also results in a very rich polymorphism, with about 20 phases known [37], whereas two of these polymorphs, namely, quartz and cristobalite, exhibit a density minimum near 1300 K, the melting point of cristobalite in addition decreasing with pressure [38]. The OH₄ and SiO₄ units bonded in tetrahedral arrangements are spatially correlated, forming infinite clusters around T_m [11].

In SiO₂, the nucleation temperature in liquid 2 is T_g , like for H₂O and all other glasses. The critical number n of atoms in an elementary supercluster is predicted in Table 3 with Eq. (3) at $T_2 = T_g$ of any liquid 2. New ordered structures are built at T_g by superclusters whose

density decreases when the “magic” number n of atoms defining the critical size of elemental (probably icosahedral) superclusters is exceeded. The value of $(1 + \epsilon_{gs})/(\theta_g - \epsilon_{gs})$ in Eq. (3) is 1.5 in all glasses. This magic number n is $751/\Delta S_m$ with $\ln K = 90$ and $N_A k_B = 8.34$ J in Eq. (3) where ΔS_m is the melting entropy in J/K/g atom [39].

The atom number n per entity increases with the reduced glass transition temperature and facilitates percolation and interpenetration. For example, for H₂O, $n = 102$ and $\theta_g = -0.50128$ and for SiO₂, $n = 505$ and $\theta_g = -0.262$. The different bonding forces between H₂O and SiO₂ atoms and molecules induce different melting temperatures T_m and enthalpies ΔH_m , which are embodied in the definition of the reduced temperature θ . Despite this feature, the reduced glass transition temperature ($\theta_g = -0.50128$) of H₂O is smaller than that of SiO₂ (-0.262) because the weakness of Si—O intertetrahedral bonds, compared with those of O—H, makes the building of supercluster structure easier.

Being proportional to $[1 + \Delta\epsilon_{lg}(\theta_g)]^3/[\Delta\epsilon_{lg}(\theta_g)]^3$, the critical number of atoms giving rise to phase 3 diverges when $\Delta\epsilon_{lg}$ tends to zero at T_g [29]. The glass state in fact results from the percolation threshold of such entities at the homogeneous nucleation temperature $T_2 = T_g$ [40].

We finally note that vitrification is very difficult to achieve in the absence of atoms of different nature in pure metals (Chapter 7.10) at the lowest $\theta_g = -0.6223$ fixed by Lindemann’s constant of 0.103, corresponding to $\epsilon_{gs0} = 0.217$ [26]. In Figure 15, the homogeneous nucleation temperatures $T_2 = T_g$ of superclusters in some strong liquids 2 are plotted as a function of their enthalpy coefficients ϵ_{gs0} governing their formation between $\epsilon_{gs0} = 0.217$ and 2. The number of different atoms also increases the glass transition temperature.

6 Perspectives

As based on glass phenomenology and nucleation thermodynamics, a two-liquid model shows the existence of a univariant first-order transition curve $T_{LL}(P)$ between two critical pressures. To complement classical

Figure 15 Reduced glass transition temperatures θ_g vs. ε_{gso} (cf. Table 3 for numbers 1–6). Formulae $\varepsilon_{gso} = (3\theta_g + 2)/(1 - \theta_g^2)$ and $\theta_g = (T_g - T_m)/T_m$ referring to Eq. (9) for $\Delta\varepsilon = 0$ and $\Pi_2 = 0$ with $\theta_{n-} = \theta_g$.

nucleation theory, an enthalpy term is introduced to account for the formation and the melting of glass nuclei through homogeneous nucleation of the liquid, instead of surface melting. The homogenous nucleation temperatures then show the thermodynamic origin of glass formation and the superheating temperatures of “ordered” liquids. Whereas these features begin to be revealed [24, references therein], overheated nuclei could even be viewed in a near future to unveil new properties of superatoms such as their melting by homogeneous nucleation instead of surface melting.

As a matter of fact, the first-order transition at T_{LL} under normal pressure induces the formation of a strong glacial phase as already observed in few materials [24]. A liquid-to-glass transition occurs for $0.017 < P < 0.55$ GPa. The existence of a pseudo-critical point calculated for $P = 0.018$ GPa is confirmed [12]. A line of first-order transitions at $P(T_{LL})$ exists for $0 < P < 0.55$ GPa in agreement with experimental results [7, 41]. Any negative pressure tends to induce crystallization near T_{LL} .

Like water, any melt could contain at least two liquid states, each one having its glass transition temperature at a homogeneous nucleation temperature T_1 or T_2 . The main glass transition would always occur at the temperature where the two ordered liquids are mixed, and a glass phase 3 was produced at $T_{g2} = T_g$.

The most interesting perspective for applications is the existence of first-order transition temperatures given by Eq. (17), leading to sharp transformations of glasses toward new equilibrium states of lower enthalpy, which may be the crystalline state, an ultrastable glass state, or a new equilibrium state of glass. These transformations can be produced by isothermal annealing each time that $\Delta\varepsilon_{lg}$, as given by Eq. (15), is equal or close to zero (cf. Figures 6, 11, and 12) with or without application of pressure. The lowest enthalpy of the ultrastable glass is obtained by vapor deposition at a well-defined temperature T_{sg} below T_g . Other first-order transitions giving rise to glacial

phases occur above T_g if $\Delta\varepsilon_{lg}$, as given by Eq. (15), is still close to zero, as exemplified by water (Figures 6, 11, and 12). These sharp transformations are difficult to achieve in bulk glasses or glass-forming melts because the exothermic enthalpies heat the sample and the condition $\Delta\varepsilon_{lg} = 0$ cannot be respected. To observe these sharp transformations, the supercooled liquid or the glass should be maintained close to the temperature of transformation. Despite this difficulty, such transformations of supercooled water have been produced in bulk samples [5–7].

Section IV. Transport Properties

Figure 1 A time immemorial illustration of the slowing-down effects of viscosity increases on mass transport: an initially yellow-hot, highly fluid basaltic lava (left) gushing down the slope of the Piton de la Fournaise volcano (La Réunion island) before cooling to a red-hot, slowly advancing, and partially crystallized magma (right). *Source:* Photos Nicolas Villeneuve.

This section is the shortest of the *Encyclopedia*, but certainly not the least important. It could have been part of the third since transport properties and their mechanisms are of course matters for physicists. But these properties deserve a special treatment owing to the fundamental kinetic control they exert on all processes involving glass-forming melts, whether industrial or natural. In industry, throughput is, for example, optimized through compromises made between faster processes and higher operating costs caused by higher temperatures and the ensuing wear of equipment. But the kinetics of all processes is ultimately limited by mass and heat transfer within the glass, which depends much on both temperature and composition as will be seen in this section.

That glass can be blown just by the pressure of human breath simply results from the Newtonian nature of the viscosity of oxide glasses, i.e. the strict proportionality between the strain rate and the stress applied. Empirically, it has long been known that viscosity is the single most important practical property of glass-forming liquids: from melting to shaping and annealing, all the operations of the glassmaker must be performed in well-defined intervals (Chapter 10.5). In nature (Figure 1), viscosity is also the key parameter that has determined the rate of mass and energy transport at all scales ever since the Earth and terrestrial planets formed 4.57 billion years ago. But an important practical difficulty underlined by J. Deubener is that no other property of glass-forming melts varies so much with temperature, at constant composition, and with composition, at constant temperature: in both cases variations can exceed 13 orders of magnitude, independently of the fact that solid and gaseous inclusions can also exert a strong influence (Chapter 4.1).

Even though viscosity is a bulk property, it is controlled in oxide melts by the mobility of network-forming cations, which vanishes at the glass transition. In contrast, the mobility of network-modifying cations can remain significant, which is why glasses can be poor electrical insulators. As described by J.-L. Souquet, ionic transport is generally ensured by the most mobile ions, i.e. the small and weakly bonded alkalis, whose motion conforms to the models of ionic transport designed for crystals, although an electronic contribution to electrical conductivity also exists in the presence of coexisting states of multivalent elements such as Fe^{2+} and Fe^{3+} between which electron transfer can occur (Chapter 4.2).

With decreasing temperatures, the increased decoupling between the mobilities of network formers and modifiers has important consequences on tracer diffusion coefficients, which also vary considerably with both composition and temperature. A considerable body of diffusion data is now available and even includes high-pressure measurements relevant to the earth sciences. It is reviewed by H. Ni and N. de Koker who emphasize the general decrease of diffusion coefficients with increasing charge, ionic radius, and polymerization state of the melt; they also point out that, in spite of the insights gained from atomistic simulations, work remains to be done to understand fully the microscopic mechanisms at play (Chapter 4.3). Contrary to the simple case of tracer diffusion, whereby a single element is considered, in many practical situations diffusion takes place between two melts of different compositions. On both sides of the diffusion front, one must consider the strong coupling between the motions of the diffusing elements that is determined by their mutual chemical affinities. The question is dealt with by M. Roskosz and E. Gouillart who explain how material fluxes in opposite directions can be coupled with Onsager generalization of Fick's equations; as an illustration, they apply this formalism to the determination of the diffusion matrices and diffusion pathways in ternary systems, from which more complicated situations can be treated (Chapter 4.4).

Heat transport must also be considered in terms of either thermal conductivity (k) or diffusivity (D), the latter differing from the former by the product of density and heat capacity. Determination of these properties is difficult at high temperatures where radiative transfer dominates. The ground has become firmer thanks to new methods examined by A. Hofmeister and A. Whittington with which decreases of both k and D with increasing polymerization have been documented; but more complex effects are seen with increasing temperatures as a result of the interplay of rising heat capacities and structural disorder in the liquid state, which in contrast hampers heat conduction (Chapter 4.5).

Among transport phenomena, diffusion lends itself the most readily to numerical simulations thanks to the possibility of tracking individual atomic pathways. As described by J. Habasaki, the complexity of the processes is clearly revealed by dynamic heterogeneities characterized by fractal dimensions and non-Gaussian dynamics as well as by a disruption of jump pathways at work in the mixed-alkali effect (Chapter 4.6).

4.1

Viscosity of Glass-Forming Melts

Joachim Deubener

Glass Science and Engineering, Institute of Non-Metallic Materials, Clausthal University of Technology, Clausthal-Zellerfeld, Germany

1 Introduction

That Babylonians had already devised an empirical means to characterize viscosity (Chapter 10.11) was a very early recognition of the fundamental role played by this property in all glassmaking operations (Chapter 1.1). The great importance of not only viscosity but also of its temperature dependence has also been very long recognized, as indicated by the terms *short* and *long* used by glassmakers to indicate the time available for forming a cooling glass gob depending on the maximum length of the piece that could be stretched without being reheated. As a clear illustration of these statements, one should remark that in this *Encyclopedia* no other physical property is mentioned more frequently and in more chapters than viscosity. By itself, this central importance justifies the rather comprehensive account that will be given here from a dual experimental and theoretical standpoint.

By definition, viscosity designates the melt resistance to flow under shear or normal stresses. In this respect, glass-forming melts distinguish themselves from all other liquids by the fact that their viscosity may vary with temperature by 14 orders of magnitude or more. It is this feature that makes it possible to give glass almost any kind of geometry in an inexpensive way. Viscosity (η_0), for instance, determines the conditions for melting and refining (0.7–1.0, in log units of η_0 in Pa·s), melt flow in furnace parts (1.0–1.5), forming and afterworking (1.5–7.0), annealing and tempering (11–14) and it also specifies the upper temperature of use (>14) [1]. In nature, viscosity plays the same fundamental role in

determining the rate of magma ascent to the surface as well as the style of volcanic eruptions, from gently effusive to dramatically explosive (Chapter 7.2).

As long as a melt is homogeneous, its flow obeys Newton's law according to which the ratio between the stress applied and the resulting deformation rate is a constant at a given temperature. Owing to their importance, the conditions to be satisfied for Newtonian viscosity are presented in Section 2. Insights into the physical origin of the fluid behavior on atomic scales are then given in Section 3, where theoretical concepts of structural relaxation are introduced and linked to experimental data on the dynamics of their structural entities. The importance to control viscosity in glass manufacturing over a wide range of more than 14 orders of magnitude requires different measuring methods, which are presented in Section 4. Engineering aspects are also a leading motivation to find an accurate description of the temperature dependence of viscosity. Recent results illuminating the subject are shown in Section 5.

The dependence on composition, which arises from the change in the type and fraction of network formers, modifiers, and intermediates, is of practical importance for industry too. These compositional trends are visualized by *isokom* temperatures of equal viscosity in Section 6. Deviations from Newtonian viscosity are observed when the time to establish a steady-state flow exceeds the timescale of liquid deformation. Under these conditions, relaxation phenomena cause time-dependent viscosity and lead to shear thinning with respect to high deformation rates. Both effects are introduced in Section 7. Finally, Section 8 will shed light on the flow of heterogeneous liquids. In particular, suspension rheology is used to describe the effective viscosity of bubble- and crystal-bearing liquids as they appear in the course of either batch melting or magmatic processes.

2 General Aspects and Definitions

Glass melts are characterized by a time-dependent response to either mechanical strain or stress. At temperatures above the glass transition T_g , they can be considered as incompressible isotropic fluids when steady-state flow obtains. Under these conditions, the flow conforms to Newton's law:

$$\tau_\sigma = \eta_0 \frac{dU}{dy}, \quad (1)$$

where the Newtonian viscosity η_0 is a constant of proportionality between the shear stress τ_σ and the derivative of the velocity component in the direction of the shear dU/dy , which is perpendicular to the displacement. In fact, only an apparent viscosity can be determined since U is measured in most experimental techniques from the change in position (angle ϕ , length l) in the direction of displacement. For a linear velocity gradient, dU/dy reduces to U/y , and the apparent viscosity η is equal to Newtonian viscosity η_0 . It is then given by the constant ratio between the applied shear stress τ_σ and the shear rate $\dot{\gamma}$ in the direction of displacement:

$$\eta_0 = \frac{1}{f} \frac{\tau_\sigma}{\dot{\gamma}}, \quad (2)$$

where f is a geometric coefficient that reflects the ratio of extensional (normal) to shear stresses (Trouton's ratio). A value $f=1$ applies for pure shear deformation (e.g. Couette and Searle-type rotational viscometers; see Figure 1), whereas $f=3$ is valid for the uniaxial elongation of a glass fiber (volume conservative flow of Poisson's ratio $\nu = 0.5$). For the latter, $\dot{\gamma}$ is replaced by the strain rate $\dot{\epsilon}$ (where $\dot{\epsilon} = d\epsilon/dt = [dl/dt]/l$, with l = fiber length) and the shear stress τ_σ by the normal stress σ , whereas for the former $\dot{\gamma}$ corresponds to the angular velocity $d\phi/dt$.

The SI viscosity unit is the Pascal second (Pa·s), where $1 \text{ Pa}\cdot\text{s} = 1 \text{ N}\cdot\text{s}/\text{m}^2 = 1 \text{ kg}/\text{s}\cdot\text{m}$. In industry, however, viscosity is still commonly expressed in terms of the CGS system whose unit is the poise (P). The conversion factor is $1 \text{ P} = 1 \text{ dPa}\cdot\text{s}$ (decipascal second) and vice versa $1 \text{ Pa}\cdot\text{s} = 10 \text{ P}$.

Newton's constitutive equation of a liquid requires the flow to be laminar; otherwise inertia would cause turbulence and the flow would become complex. Laminar flow means that a constant friction arises in a fluid between neighboring particles that are moving at different velocities in parallel layers. This situation obtains when values lower than 1 are found for the Reynolds number, which defines the ratio of inertial to viscous forces as $Re = \rho VL/\eta$ (ρ = density, V = fluid velocity, L = characteristic linear dimension). If this condition is not met, more general

Figure 1 Flow of Newtonian and non-Newtonian liquids as characterized by stress (a) and viscosity (scaled logarithmically) (b) vs. strain rate. Inset: sketch of Newtonian laminar flow in a Searle-type rheometer with a stationary outer cylinder and a rotating inner cylinder (no-slip condition). Gradient in the angular velocity dU/dy perpendicular to the direction of the shear forces and the angular velocity $d\phi/dt$.

non-Newtonian formalisms must be used. If the stress is very quickly applied or if the liquid is heterogeneous (e.g. suspension, foam, emulsion), the complex flow of glass-forming melts can, for instance, be described with power law equations [2]:

$$\tau_\sigma = \tau_{\sigma 0} + K \dot{\gamma}^n, \quad (3)$$

where $\tau_{\sigma 0}$ is the yield stress, K the flow consistency and n the exponent of the strain rate. In contrast to Newtonian fluids ($\tau_{\sigma 0} = 0$), plastic materials begin to flow only when the applied stress exceeds this minimum value $\tau_{\sigma 0}$. If the

non-Newtonian liquid has no yield stress, then the apparent viscosity η is a function of its current deformation rate:

$$\eta = \frac{1}{f} \frac{\tau}{\dot{\gamma}} = K \dot{\gamma}^{n-1}. \quad (4)$$

For $n = 1$, Eq. (4) reduces to Newton's law, whereas for $n < 1$ and > 1 the liquid is shear thinning ($\eta < \eta_0$) and shear thickening ($\eta > \eta_0$), respectively. These differences between Newtonian and non-Newtonian liquids are summarized in Figure 1.

3 Structural Aspects

Above the glass transition, structural relaxation is much faster than usual times of observation so that Newtonian liquids do not retain any memory of their flow history. Understanding the physical origin of viscous flow in glass-forming melts requires insights onto the dynamics of their structure, however, which is by definition controlled by the structural relaxation time τ (Chapter 3.7). At the atomic scale, theories generally assume that energy is required to overcome potential energy wells delineated by the bonds connecting the structural elements that undergo flow. The flow causes irreversible dissipation of mechanical energy (internal friction) since as soon as it is stopped the liquid returns to its initial mechanical state.

With respect to viscous flow, the relevant structural elements are atoms, molecules, or network fragments (polyhedra). They are nonperiodically distributed in space and linked to one another, creating a potential energy landscape where minima are separated by barriers having varying heights and shapes (Chapter 3.9). These elements are thermally agitated, performing small motions around their equilibrium positions. In metastable melts at low enough temperatures (i.e. close to the glass transition), a sufficiently large stress is necessary to overcome the relevant potential energy wells, whereas in stable melts at very high temperatures (i.e. far above the liquidus), thermal agitation is significant and induces fast displacements over distances that can reach the size of an element (with trajectories resembling those of a Brownian movement). Under these conditions, relaxation times are relatively short ($\tau < 10^{-12}$ seconds), and one would expect a smooth increase of the viscosity with decreasing temperature since the mean thermal velocity of an atom decreases with $T^{0.5}$. As stated in Section 5, however, the actual dependence of viscosity on temperature is orders of magnitude steeper.

As a matter of fact, the slowing down of the relaxation dynamics correlates with a considerable broadening in the time dependence of the correlation function. A two-step decrease is evident. At short timescales, atoms can move by fast dynamics in a collision regime (Brownian atoms); at intermediate timescales, they remain thermally agitated but become trapped locally (large displacements being prevented), leading to a plateau in the correlation function; at relative large timescales, they can escape from their neighborhood by means of faster β -relaxation and slower α -relaxation, whereas the correlation function decays in a stretched exponential form (Kohlrausch–William–Watts type) [3]. The stretching exponent indicates the dynamically heterogeneous nature of the relaxation in glass-forming melts, which can be interpreted in two different ways: (i) either of different atoms showing different dynamical timescales in a spatially homogeneous melt (ii) or of a spatially heterogeneous melt in which all atoms of a given local environment relax at the same timescale, these timescales differing from one environment to another. The multi-atom problem of dynamic heterogeneity is echoed in terms of cooperative rearranging regions by Adam and Gibbs [4].

As for the temperature dependence of viscosity, it means that fast-collision dynamics are prevalent far above the liquidus, whereas α -relaxation is predominant close to the glass transition. In sodium silicate melts, ^{23}Na spin–lattice relaxation NMR experiments [5] indicates that the dynamics of Na hopping follows the timescale for stress relaxation by viscous flow at temperatures above T_1 ($\eta = 10^1$ Pa·s). At lower temperatures the timescale of β -relaxation processes meets that of viscous flow, whereas the crossover temperature for the β -to- α transition is close to T_3 for a common soda-lime-silicate melt (see Section 5). For temperatures below T_3 , viscous flow is controlled by the timescale of α -relaxation, which controls the dynamics of the bridging O–Si bond connecting two silica tetrahedra [6]. Below the glass transition, isostructural viscosity is finally observed since the timescale of α -relaxation and then exceeds that of the experiment.

Emphasizing the importance of the bridging oxygen dynamics, Bockris et al. [7] identified network fragments such as $\text{Si}_3\text{O}_9^{6-}$ rings as basic “flow units” in metastable alkali silicate melts, whereas Toplis et al. [8] assigned subsystems of approximately 10 “activated” tetrahedra at the glass transition as an effective dynamic length scale. In any case, a decrease in the dynamic length scale with temperature can be assumed because experiments show that the Stokes–Einstein and Eyring equations (both relating self-diffusion coefficient to viscosity) break down at

temperatures below $\approx 1.2 T_g$, where viscous flow is decoupled from the length scales of diffusion.

4 Technological Aspects

4.1 Measuring Methods

It should not come as a surprise that a physical property that varies by 14 orders of magnitude cannot be measured with a single experimental method. Two different kinds of rheometers or viscometers are actually used depending on the predominantly liquid- or solid-like response of the material when subjected to a stress (Tables 1 and 2) [9]. The first operates in viscosity ranges relevant to the melting, fining, and working processes ($\eta_0 < 10^6$ Pa·s) and involve melt shearing under controlled conditions of either strain rate (rotating concentric cylinders) or stress (rising bubbles and falling spheres). The second kind is applicable to highly viscous melts ($\eta_0 > 10^6$ Pa·s) in ranges at which deformation and annealing are performed industrially (Figure 2). Viscosity is then frequently determined by the rate at which a glass specimen of defined geometry deforms under a constant load (with a combination of shear and volume stresses), as made with ball-penetration, beam-bending, and cylinder-compression experiments (Table 2).

Application of these methods relies on the assumptions that the flow is laminar and that η depends neither on time or deformation rate, i.e. that Eq. (2) is valid ($\eta = \eta_0$). The former has to be considered if glasses are deformed close to the glass transition ($\eta_0 = 10^{11}$ – 10^{15} Pa·s), where relaxation times are large (see Section 7)

Figure 2 Viscosity–temperature range of industrial processes (boxes) and fixed points of viscosity T_n (with $\eta_0(T_n) = 10^n$ Pa·s) for a soda-lime-silica glass.

so that increasingly long measuring times t become necessary to achieve complete relaxation. In practice, for isothermal treatments, these holds should be $t > 10^{2.5}$ seconds at T_{11} with $\eta_0(T_{11}) = 10^{11}$ Pa·s, $t > 10^{3.5}$ seconds at T_{12} , $t > 10^{4.5}$ seconds at T_{13} , etc., which means that under standard laboratory conditions, very high viscosities ($\eta_0 > 10^{15}$ Pa·s) seem unattainable. Accordingly, when a glass specimen is heated at a constant rate such as at 5 K/min, equilibrium values of the viscosity are derived from Eqs. (8) to (12) if $\eta < 10^{9.5}$ Pa·s.

Owing to the very strong temperature dependence of viscosity, accurate measurements require temperature gradients within the sample investigated to be less than about 0.1 and 1 K near the glass transition and above the liquidus, respectively. Finally, phase transitions such as partial evaporation or crystallization are generally incongruent processes, whose resulting composition changes cause marked viscosity variations. A simple way to make sure that they are not problematic during long, high-temperature measurements thus is to check that the same viscosities are obtained at given temperatures at the beginning and end of the experiments.

4.2 Gas Bubble Rise

This method is specially relevant to glass refining because it relies on measurements of the terminal ascent velocity $(dh/dt)_0$ of a gas bubble in a translucent crucible (silica, corundum) as recorded by a camera system through the observation window of a high-temperature furnace. Under low Reynolds numbers (<1), the ascent of small gas bubbles ($2r < 2\text{--}3\text{ mm}$) obeys Hadamard–Rybczynski's law, Eq. (5) in Table 2, whereas that of larger ones deviates from it because of bubble deformation (oblate ellipsoidal and spherical cap).

4.3 Falling Sphere

If an observation furnace is not available, a small noble metal sphere (Pt, Pt/Rh) may be dropped in the hot melt where it falls for a time t . The penetration depth h of the sphere until the melt is quenched is measured on longitudinally cut quenched samples or continuously by *in situ* X-ray scans. Under low Reynolds numbers (<1), the terminal velocity $(dh/dt)_0$ obeys Stokes' law (Reynolds number-to-drag coefficient ratio is 24), but edge effects have to be accounted for if capsules and narrow crucibles are used (Table 2). The method is time consuming because an experiment yields the viscosity at a single temperature. Hence, it is now mainly used for high-pressure determinations for which no other methods are applicable.

4.4 Rotating Cylinder

The method is the most common for fluid melts ($\eta < 10^3\text{ Pa}\cdot\text{s}$). The torque M needed to maintain a constant rotational speed $(d\phi/dt)_0$ is measured for either a rotating spindle immersed in the hot melt of a fixed container (Searle type) or a rotating crucible in which a fixed spindle is immersed (Couette type). A correction to account for the drag of the container walls is in principle necessary (Eq. 7 of Table 2), but in practice one determines

deviations from ideal geometric conditions by running initially the system with liquids (reference oils) of certified viscosity at room temperature. Measurements are thus relative and not absolute.

4.5 Fiber Elongation

Near the glass transition, viscosity can be determined from the rate of elongation of a fiber either under its own weight (one face fixed) or under an external load. In the former, the fiber is only partially heated over its length (see fixed points of viscosity; Section 4.10), whereas in the latter the entire fiber is placed inside a furnace. A fiber of length l with rounded tips is then clamped between two supports and elongated in a vertical or horizontal furnace at a constant force. If a weight is used, the deformation stresses increase because of contraction of the fiber diameter. A spiral disk that maintains a constant stress level compensates this effect. For small fiber (mass $m < 4\text{ g}$) in a vertical stage, the elongation rate dl/dt has to be corrected for self-loaded elongation and surface tension-induced shrinkage. The viscosity for a full-length heated fiber of mass $> 4\text{ g}$ is given by Eq. (8).

4.6 Parallel Plate

In this method, the deformation of a cylindrical disk uniaxially compressed is measured in a vertical tube furnace after a hold time for thermal equilibration. Rigid pistons or push rods exert controlled strain rate or load conditions. Depending on the slip conditions between the glass faces and the contact material, barreling of specimen may be observed. For perfect non-slip conditions and a sample with an initial diameter-to-height ratio ≥ 1 , the Gent solution is given by Eq. (9) where h is the instantaneous height and dh/dt is the axial deformation rate. Owing to the high exponential dependence of the viscosity on the height in Eq. (9), deviations from ideal stiffness of the apparatus during compression must be considered.

4.7 Beam Bending

The resistance to bending of a beam is yet another measure of viscosity. The symmetric three-point bending method is the most common. A glass beam of support span l is centrally loaded inside a furnace after a hold time for thermal equilibration. Hagy's solution of the measured deflection rate dh/dt at midpoint for a rectangular beam of cross-sectional height h and width b (moment of inertia $I_c = h^3b/12$) is given by Eq. (10).

Table 2 Methods of measuring viscosity.

Method	Schema	Range ($\log \eta$)	η (Pa·s) =	Equation
Gas bubble rise		<2	$\frac{r^2 g \rho_{\text{melt}}}{3(dh/dt)_0}$ ^a	(5)
Falling sphere		<4	$\frac{2r^2 g (\rho_{\text{sphere}} - \rho_{\text{melt}}) C_1}{9(dh/dt)_0}$ ^b	(6)
Rotating cylinder		1–5	$\frac{MC_2}{(d\varphi/dt)_0}$ ^c	(7)
Fiber elongation		>6	$\frac{mgl}{3\pi r^2 (dl/dt)}$	(8)
Parallel plate		>7	$\frac{2\pi mgh^5}{3V(2\pi h^3 + V)(dh/dt)}$	(9)
Beam bending		>7	$\frac{gl^3 (m + hbl\rho_{\text{glass}}/1.6)}{144I_c (dh/dt)}$	(10)
Sphere penetration		>8	$\frac{3mg}{16(2rh)^{0.5} (dh/dt)}$	(11)
Rod torsion		>11	$\frac{2lM}{\pi r^4 (d\varphi/dt)}$	(12)

Keys: r = radius (m), ρ = density (kg/m^3), g = gravitational acceleration (m/s^2), V = volume (m^3), l = length (m), h = height (m), b = width (m), m = mass (kg), M = moment of force (torque) ($\text{N}\cdot\text{m}$), I_c = moment of inertia (see text) C_1 and C_2 .

^a Solution of Hadamard–Rybczynski's equation for a fluid sphere and a Reynolds number-to-drag coefficient ratio of 16, which allows for slip velocities at the bubble surface.

^b Faxen correction term $C_1 = 1/[1 + 2.4 (r_{\text{sphere}}/r_{\text{container}})]$ for $r_{\text{sphere}}/r_{\text{container}} < 0$, to which must be added a correction for the penetration depth $h_{\text{melt}} = h_{\text{glass}}[\rho_{\text{melt}}/\rho_{\text{glass}}]^{1/3}$ to account for the difference in the specific volumes of the melt and the glass.

^c Correction for the drag of the container walls given by a Faxen-type term. For a rotating spindle of length l (Searle type), it is

$$C_2 = \left(r_{\text{container}}^2 - r_{\text{spindle}}^2 \right) / \left[8\pi l r_{\text{spindle}}^2 r_{\text{container}}^2 \right].$$

4.8 Sphere Penetration

In this method, a rigid high-precision microsphere of radius r (e.g. sapphire with $r < 1\text{--}2\text{ mm}$) is fixed between the lower end of a transducer rod and the surface of the glass specimen in a vertical furnace setup. The rod is loaded after a hold time for thermal equilibration and the sphere starts to penetrate at a rate dh/dt , where h is the penetration depth into the glass. The viscosity is then given by the solution of Douglas et al. for $r \gg h$ of Eq. (11).

4.9 Rod Torsion

A rod of length l and radius r is fixed at one end and the opposite end is rotated with a torque M to maintain the angular velocity $d\phi/dt$. In cross sections along the heated length l of the rod, the angular velocity decreases from $d\phi/dt$ at the rotating part to zero at the fixed part. The viscosity is given by Trouton and Andrews' solution to Eq. (12) for a rod subjected to torsion in either horizontal (limited by bending at higher temperatures) or vertical (limited by flowing at lower viscosities) positions.

4.10 Standard (Fixed) Points

In industry, determination of viscosity over the entire temperature range relevant to production (from the batch melting to the cooling regime) is time consuming. In practice, therefore, glass technologists frequently make only a few measurements (at least 3) to compute the entire viscosity–temperature curve with any of the three-parameter equation presented in Section 5. Following standard procedures, they rely on standard points, also referred to as viscometric fixed points. A standard point is by definition an isokom temperature. Depending on the geographic region (market), slightly different standards are selected today in industry as seen in Table 1 with ISO, JIS, and ASTM.

Because the use of fixed points still requires three individual measurements, Scholze [10] proposed a single heating microscopy experiment on a small glass volume (monolith or powder compact) as an even faster method to determine the entire viscosity–temperature relationship. The method relies on the small temperature coefficient of the surface energy of silicate liquids. The onset of shrinkage (glass powder compacts), the rounding of edges (bulk glass cubes/cylinders), and the appearance of sphere and half-sphere shaped geometries of the sessile drop then take place within narrow viscosity intervals independent of the composition of technical glasses (soda-lime-silicate and borosilicate). All these characteristic geometries (silhouettes) can thus be observed in a microscopy experiment as the glass specimen is heated at a constant rate on an alumina support.

Besides, other fixed points such as the flow (T_2) and the melting (T_1) temperatures are used in industry to characterize the fusibility of silicates (slags, enamels, ashes) following in-house and product-specific procedures. In most of them the volume of the glass specimen is defined, which will not enable an exact determination of viscosity since differences in density and surface tension of glasses are not taken into account. For soda-lime-silica melts, the viscosity values ($n = \log \eta_0$) of the isokom temperatures used in industry are compiled in Table 1.

5 Temperature Dependence of Viscosity

5.1 Viscosity Regimes

Viscosity varies so much with temperature that its ratio between the liquidus T_{liq} and glass transition temperatures T_g is about 10^6 (silica glass), 10^{11} (soda-lime-silicate), and 10^{15} (metal alloys). When a broad temperature range is considered (Figure 3), the Newtonian flow of glass-forming liquids can be divided into three parts [11].

Below the glass transition (stage I of Figure 3), the average time required for structural relaxations τ exceeds the observation time t , and the viscosity follows an Arrhenian law. A constant activation energy indicates that relaxation involves only vibrational contributions, configurational

Figure 3 The three viscosity regimes of soda-lime-silica melts of similar composition (window glass). Stage I ($T < T_g$): isostructural Arrhenian viscosity of the non-relaxed liquid, the upper and lower lines referring to the two limiting fictive temperatures. Stage II ($T_{\text{liq}} > T > T_g$): non-Arrhenian viscosity, with a VFT fit through the data. Stage III ($T > T_{\text{liq}}$): Arrhenian viscosity, with a linear fit through the data with $\eta_{\infty} = 10^{-3.5}\text{ Pa}\cdot\text{s}$. Crossover temperature assumed to be close to T_{liq} ($\approx 1015\text{ K}$).

Figure 4 The *hard* and *soft* character of a variety of glass-forming liquids as determined by the nature of bonding: Arrhenius plot of the viscosity of the main network-forming oxides P_2O_5 , SiO_2 , GeO_2 , and B_2O_3 (bases of the phosphate, silicate, germanate, and borate glass families, respectively), of technical silicate melts (soda-lime-silica, borosilicate, and lead silicate), and of glass-forming metallic (Zr–Ti–Cu–Ni–Be alloy), van der Waals (glycerol, *o*-terphenyl), and ionic (K,Ca-nitrate) liquids. Dashed lines: VFTH fits through the data to approximate T_{12} for those liquids for which viscosity data are not provided.

changes being left unexplored. The viscosity of such an unrelaxed liquid is called isostructural. It is measured in a rheometric experiment instantaneously after a sudden temperature change. In this way the activation energy at constant structure may be obtained – *constant structure*, meaning here constant configurational entropy, free volume, packing density, or any other parameter embodied in a particular model. In the glass transition range (GTR), the observation and relaxation times become similar so that one can monitor changes

in viscosity toward its equilibrium value during long enough experiments.

Between T_g and T_{liq} (stage II of Figure 3), the observation time t is in general longer than τ . For most glass-forming liquids, the viscosity becomes non-Arrhenian (Figure 4). In the Arrhenius expression (Eq. (13)), a temperature dependence of the activation energy $\Delta E = \Delta E(T)$ is thus required:

$$\eta_0 = \eta_\infty \exp\left(\frac{\Delta E(T)}{kT}\right), \quad (13)$$

where η_∞ is the viscosity at infinite temperature and k is the Boltzmann constant. From T_g to T_{liq} , viscous flow is governed by configurational contributions to cooperative rearrangements, which involve all atoms of the rearranging regions. Besides the change in concavity of the viscosity–temperature curves (Figure 4), one observes a shift to higher temperatures with increasing bond strength, ranging from weak van der Waals to strongly covalent bonds. On this basis, glass technologists distinguish *soft* from *hard* glasses, which have high and low isokom temperatures, respectively.

Above the liquidus (stage III of Figure 3), the variation of viscosity with temperature in the third region is Arrhenian again since configurational contributions are less dominant and the rearrangement is governed by the local atomic excitations, which goes in line with a more disassociated state of glass-forming liquids at high temperatures. The atomic vibration period τ between successive assaults to pass the energy barrier is on the order of 10^{-14} seconds as $T^{-1} \rightarrow 0$. Maxwell's equation then yields $\eta_\infty = 10^{-3.5}$ Pa·s for glass-forming silicate melts with a shear modulus at infinite frequency G_∞ of about 30 GPa.

5.2 Viscosity–Temperature Relationships

Equations with three constants have been developed to account for changes with temperature in the size of the activated volume, i.e. for the deviation from an Arrhenian temperature dependence of the viscosity (Table 3).

Table 3 Frequently used three-parameter (A , B , C) equations to represent the temperature dependence of viscosity between T_g and T_{liq} .

Name (acronym)	Year	$\log \eta_0 =$	Equation	Ref.
Vogel–Fulcher–Tammann–Hesse (VFTH)	1921–1926	$A_1 + \frac{B_1}{T - C_1}$	(14)	[12]
Adam–Gibbs (AG)	1965	$A_2 + \frac{B_2}{T \ln(T/C_2)}$	(15)	[4]
Avramov–Milchev (AM)	1988	$A_3 + \left(\frac{B_3}{T}\right)^{C_3}$	(16)	[17]
Mauro–Yue–Ellison–Gupta–Allan (MYEGA)	2009	$A_4 + \frac{B_4}{T} \exp\left(\frac{C_4}{T}\right)$	(17)	[18]

Among these the empirically Vogel–Fulcher–Tammann–Hesse (VFTH) equation (14) is most frequently used [12]. This equation relates $\Delta E(T)$ to $1/(T - C_1)$, an assumption that leads to a viscosity divergence as $T \rightarrow C_1$. Different theoretical models have been proposed as the basis of the VFTH equation. They rely on the assumption that activation energy depends either on free volume [14–16] or on configuration entropy $S^{\text{conf}}(T)$, i.e. $\Delta E(T) \propto S^{\text{conf}}(T)^{-1}$ [4].

Since both vibrational and configurational entropy may contribute to entropy changes, different approaches have been proposed to extract the configurational part in the Adam and Gibbs (AG) model. The solution for $S^{\text{conf}}(T)$ is, for instance, given by Eq. (15) for the assumptions that the isobaric heat capacity ΔC_p is temperature independent and that a glass below T_g and the corresponding liquid above T_g have the same vibrational entropy, that is, $S^{\text{conf}}(T) = S(T) - S^{\text{vib}}(T)$. In contrast to the AG approach, the Avramov–Milchev (AM) equation (16) is based on an atomic hopping model, i.e. viscosity is assumed to depend on the total entropy $S(T)$, not on configuration entropy only [17]. This model assumes a constant jump frequency (10^{14} seconds $^{-1}$) for activated transitions and a temperature-dependent Poisson distribution for the local potential energy barrier opposing viscous flow. This leads to a stretched exponential dependence of viscosity with temperature, where the stretching exponent C_3 represents the kinetic fragility (see Section 5.2) of the melt. Mauro, Yue, Ellison, Gupta, and Allan based their viscosity equation (17) on the Adam–Gibbs model but related the configurational entropy to the topological degrees of freedom each atom can access [18].

In 1984 Richet [19] showed that the verification of $S^{\text{conf}}(T)$ of the AG model can be carried out by an additional calorimetric experiment. In his approach $S^{\text{conf}}(T)$ is determined from the sum of its value at the glass transition $S^{\text{conf}}(T_g)$ plus the additional configurational entropy produced with increasing temperature from T_g to T . The former term is the effective residual entropy (by assuming ergodicity of the system at $T \leq T_g$, i.e. $S^{\text{conf}}(T_g) = S_{\text{glass}}(0)$), whereas the latter term is found by the integration of the configurational heat capacity $\Delta C_p^{\text{conf}} = a + bT$, which is the heat capacity increment at T_g ($\Delta C_p^{\text{conf}} = C_{p\text{liquid}}(T) - C_{p\text{glass}}(T_g)$) such that $S^{\text{conf}}(T) = S^{\text{conf}}(T_g) + a(\ln[T/T_g]) + b(T - T_g)$. Richet's solution for $S^{\text{conf}}(T)$ is given by Eq. (18) where the constants a , b of the linear heat capacity function and T_g are to be derived from calorimetric experiment through the GTR [19]:

$$\log \eta = A_6 + \frac{B_6}{T \left(S_{T_g}^{\text{conf}} + a \ln(T/T_g) + b(T - T_g) \right)} \quad (18)$$

Figure 5 Adam–Gibbs (AG) linear representation of the temperature dependence of the viscosity of two calcium borosilicate (E-glass) melts (Chapter 1.5).

If additionally $S^{\text{conf}}(T_g)$ is known from calorimetry for the glass under consideration, then Eq. (18) reduces to a two-parameter (A_6 , B_6) equation, i.e. a plot of $\log \eta$ vs. $(TS^{\text{conf}})^{-1}$ requires only linear fitting through the data (Figure 5).

5.3 Scaling with Temperature and Master Diagrams

In general, the ratio of the activation energy of stage II to III is ≥ 1 as illustrated by the change in slope in the Arrhenius diagram (Figure 4). The concavity of the viscosity–temperature curve depends on the nature of the glass-forming liquid, which ranges between the two limiting groups of 3-D connected networks of covalent bonded tetrahedra (small change in slope) and molecular/ionic liquids and liquids with hydrogen bonds (large change in slope). Within this classification an increase in the curvature is observed with decreasing bonding dimensionality and decreasing bond strength, which represents the transition from *long* to *short* glasses.

Viscosity in the GTR was analyzed by Nemilov [20] ($\Delta E(T_g)$) and Laughlin and Uhlmann [21] (scaling to T_g/T) to distinguish between these groups. In 1985 Angell [22] introduced the names *strong* and *fragile* glass formers to reflect the stability of their short- and medium-range order against temperature-induced structural degradation. The strong–fragile pattern with a range of kinetic fragilities $m = [d(\log \eta)/d(T_g/T)]_{T_g}$ varying from ≈ 17 (SiO_2) up to 200 (van der Waals liquids) is represented in T_g -scaled Arrhenius plots of the liquid viscosities (Figure 6). For this purpose, $\eta(T_g)$ must be defined with respect to the heating rate and measurement frequency.

Figure 6 From strong to fragile liquids: fragility (m) and T_g/T -scaled representations of the temperature dependence of the viscosity of a variety of glass-forming melts (T_g defined as T_{12}). Viscosity and T_{12} data from Figure 4. Isofragility lines shown for $\eta_0(T_g) = 10^{12}$ Pa·s and $\eta_\infty = 10^{-5}$ Pa·s indicated by arrows.

If the average relaxation time τ (T_g) = 10^2 seconds is used, then the viscosity (in log units) at T_g is 10.5 for molecular liquids and 12.5 for silica glass. With $T_g = T_{12}$, i.e. $\eta(T_g) = 10^{12}$ Pa·s, Eqs. (19)–(21) can be rewritten to fit viscosity data to the reduced temperature scale (T_g/T) directly from the parameters η_∞ , m , and T_g (Table 4). Alternatively, the liquid fragility can be expressed by the parameters $C_3 = m/(12 - \log \eta_\infty)$ [23], $F = C_1/T_g$ [24], and $F_{1/2} = 2T_g/T_{1/2} - 1$ with $\log \eta_0(T_{1/2}) = (12 - \log \eta_\infty)/2$ [25].

Further, one can represent the departure from Arrhenius laws by plotting the viscosity (in log units) against $dT/d(\log \eta_0)$. This type of scaling is frequently used to approximate limits with respect to specific working processes such as drawing, blowing, and casting as the

isokomal workability is proportional to the change in temperature per viscosity decade. Thus, this type of temperature scaling visualizes best the technologist's classification of *long* [large $dT/d(\log \eta_0)$] and *short* [small $dT/d(\log \eta_0)$] glasses (Figure 7).

A master diagram has been developed, which collapses the different $\eta(T)$ dependences of Figure 6 onto a single curve over the stage II viscosity interval [26] through incorporation of the crossover temperature T_c (which indicates the α -to- β transition in governing the rheology) as a second reference temperature into the temperature scaling. The resulting master curve is represented by the dimensionless plot $\log[\eta(T)/\eta(T_g)]$ vs. $[T_c/(T_c - T_g)] \times (T_g - T)/T$ of Figure 8 where T_c is determined from relaxation studies or, if not provided by an independent experiment, estimated from fits of the viscosity to the general dependence of Figure 8.

6 Composition Dependence

6.1 Pure Oxide and Binary Silicate Melts

Oxide glasses are the focus of this section owing to their technological importance. In general the viscosity depends much more on composition and structure near the glass transition (T_{12}) than above the liquidus ($<T_3$) where data tend to converge. Isokom temperatures are used to visualize the changes in viscosity with composition.

The isokoms of glass-forming melts do not correlate simply with the activation energy of viscous flow ΔE or other interatomic energies, e.g. SiO_2 (1450; 525), BeF_2 (590; 250), and Se (300; 1670) with T_{12} in K, ΔE in kJ/mol [20]. A prediction based on metal–oxygen bond strength and the dimensionality of the polyhedral linkage also fails for pure oxide melts with a spatially continuous network for which T_{12} (Figure 4) is 1401 K (SiO_2), 819 K (GeO_2), 550 K (B_2O_3), and 537 K (P_2O_5). In addition, the isokom temperatures of these oxides are strongly affected by impurities. Traces of other elements are mainly introduced by the raw materials and contamination during the

fusion process. As classified by Brückner [27, 28] for silica glass (types I–VII), the nature and fraction of impurity atoms play a crucial role in decreasing viscosity. Leko et al. [29], for instance, showed that small fractions of

Figure 9 The markedly differing effects of additions of Na_2O to SiO_2 on the T_{12} , T_6 , and T_3 isokoms. Immiscibility dome (solid curve) and spinodal (dashed curve) included. Trend lines as guides to the eyes.

sodium atoms in silica melts lead to a dramatic decrease in the T_{12} isokom whereas the effect is less pronounced at higher temperatures (Figure 9). The main structural feature affecting viscosity is the formation of nonbridging oxygens (NBO), which depolymerize the tetrahedral network (Chapter 2.4).

When increasing the concentration of network-modifying ions from the impurity level to constitutional fractions (binary silicate melts), one has to take into account microstructural effects caused by the presence of stable and metastable immiscibility regions on the silica-rich part of binary $\text{M}^{2+}_{2/z}\text{O}-\text{SiO}_2$ ($\text{M} = \text{Li}^+, \text{Na}^+, \text{Ca}^{2+}, \text{Sr}^{2+}, \text{Ba}^{2+}$) systems. The steep decrease in the T_{12} isokom is close to the spinodal boundary (12–16 mol % Na_2O) at which the silica-rich phase ceases to be continuous (Figure 9). The influence of divalent cations such as CaO , MgO , and ZnO at low temperatures departs from that of the alkalis. A steeper viscosity–temperature curve is observed because the T_{12} isokom increases with CaO and ZnO contents whereas the opposite effect holds for the T_3 isokom. These oxides are thus said by technologists to *shorten* the glass. The influence of MgO is similar to CaO , but at high temperatures (T_3) NBO formation becomes partly ineffective because of a reduction of the oxygen coordination from six to four. The addition of heavy post-transition metal cations such as Pb^{2+} to silica causes an even stronger viscosity decrease than by alkaline earth cations of similar size (Sr^{2+}) since their higher electron polarizability makes shear easier.

Figure 10 Effects of Na_2O content and induced changes in boron speciation on high- and low-temperature isokoms of the B_2O_3 – Na_2O system. Viscosity increases caused by BO_3 –to- BO_4 conversion delineated by the dashed domain.

Network-modifying oxides act as fluxes when mixed with SiO_2 , GeO_2 , and P_2O_5 . When added to B_2O_3 , Na_2O in contrast increases isokom temperatures up to about 20 mol % Na_2O at low temperatures (Figure 10) because of the conversion of triangular BO_3 groups into BO_4 tetrahedra stabilized by Na^+ . This effect is known as the boron anomaly (Chapter 7.6). At both higher Na_2O fractions and temperatures, however, NBOs are increasingly formed in a competitive process, which leads to the expected decrease in viscosity.

In phosphate melts, the viscosity is also closely related to the structure, which is a chain-like linkage for the metaphosphate compositions of monovalent $[\text{MPO}_3]$, divalent $[\text{M}(\text{PO}_3)_2]$, and trivalent $[\text{M}(\text{PO}_3)_3]$ metal cations. Eisenberg et al. [30] have early shown that an increase of the T_{12} isokom is caused by the high attractive forces of the metal cation at the terminal oxygen (TO), i.e. by an increasing ratio of the charge-to-metal oxygen distance $z/R_{\text{M-O}}$ (Figure 11). A structural explanation is that each metal cation has at least four terminal oxygens (TO) at the same or neighboring phosphate chains [31] and that removal of at least one TO at a time from the coordination sphere of the metal cation enables internal rotation of phosphate chains and, thus shear, to take place.

6.2 Ternary and Multicomponent Silicate Melts

The melts commonly used in the float- and container-glass industry are close to the archetypal ternary composition 16 Na_2O ·10 CaO ·74 SiO_2 (wt %). But actual

Figure 11 Influence of the charge-to-distance ratio $z/R_{\text{M-O}}$ on the viscosity of metaphosphate melts ($\text{O/P} = 3$) with mono- ($z = 1$), di- ($z = 2$), and trivalent ($z = 3$) metal cations M .

compositions include further former, modifier, and intermediate metal oxides and volatiles (sulfur, water) as exemplified by a typical float-glass composition of 71 SiO_2 , 0.5 Al_2O_3 , <0.1 Fe_2O_3 , 4 MgO , 10 CaO , 14 Na_2O , 0.1 K_2O , 0.3 SO_3 . Within limited compositional ranges, the effects on isokom temperatures of changes in oxide fractions can be described by linear functions (Chapter 1.1). The coefficients (oxide factors) for T_2 are positive for SiO_2 and Al_2O_3 , Fe_2O_3 and negative for MgO , CaO , Na_2O , and K_2O , whereas at low temperatures (T_{12}) the oxide factors for MgO and CaO are in contrast positive.

The viscosity of melts with two network-forming oxides has been studied systematically ever since borosilicate glass was introduced by Schott in the second half of the nineteenth century. Owing to the maximum in the fraction of BO_4 groups and the absence of NBO, the isokoms along the SiO_2 – $\text{Na}_2\text{O} \times 5.25\text{B}_2\text{O}_3$ tie line are important to the glass industry. At lower temperatures, however, an immiscibility region obtains with an upper critical temperature of about 1033 K so that isokoms can no longer be defined in view of the biphasic character of the Na_2O – B_2O_3 – SiO_2 metastable liquids [32].

Another system with two network former oxides relevant not only to industry but also to geochemistry is $\text{M}^{z+}_2/\text{zO}$ – Al_2O_3 – SiO_2 where Al^{3+} can replace Si^{4+} in tetrahedral sites if charge-compensated by alkali or alkaline earth cations (Chapter 2.4). For the molar ratio $\text{Al}_2\text{O}_3/(\text{Al}_2\text{O}_3 + \text{M}^{z+}_2/\text{zO}) = 1$ of the meta-aluminous composition, a

Figure 12 Influence of the $\text{Al}/(\text{Na} + \text{Al})$ ratio and associated change in aluminum speciation on the T_{11} and T_3 isokoms of sodium aluminosilicate melts of constant SiO_2 content (75, 67 and 50 mol %). The trend lines as guide to the eyes. Maximum shifting with increasing temperature to the peraluminous region.

fully polymerized network is expected with a maximum isokom temperature for melts of constant SiO_2 fraction. A maximum is actually observed for sodium aluminosilicate melts at high temperatures (T_3), but it is located slightly at the peraluminous side, whereas only a plateau is visible at low temperatures for the T_{11} isokom (Figure 12). Depending on the type of charge-compensating metal cation, the shift is caused by the presence of fivefold coordinated Al species [33] and (Si,Al) triclusters [34], which are involved in the flow mechanism of peraluminous melts near the meta-aluminous join. Likewise, structural investigations in the $\text{Na}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system at high temperatures indicate that the NBO fraction per tetrahedron (NBO/T) is minimum but not zero for the meta-aluminous composition [35].

6.3 Effects of Water

Water is a strong fluxing agent. Its solubility varies slightly with temperature but strongly with composition and especially with pressure since it increases initially approximately as the square root of the water pressure. As a result, solubilities higher than 10 wt % (or than 25 mol %, on an oxide basis) are observed at pressures on the order of 500 MPa (5 kbar). But determining the effects of large water contents of viscosity has long been hampered by the difficulty of high-pressure measurements.

The situation thus changed when it was recognized that high-pressure experiments could be restricted to the synthesis of hydrous samples whose viscosities could then be measured at room pressure down to $10^{9.5}$ Pa·s, before the kinetics of exsolution becomes significant, and could even be extrapolated to high temperatures by appropriate means [36].

Along with previous data for low water contents, the wealth of data obtained in this way has been interpreted in terms of the coexistence of structurally bonded OH groups and molecular $\text{H}_2\text{O}(\text{m})$ in the silicate network [37]. The solubility of these species depends on composition and is strongly nonlinear for a total water content below ≈ 2 wt % but linear above this value [38]. As for the OH/ $\text{H}_2\text{O}(\text{m})$ ratio, it positively correlates with temperature [39]. In practice, this ratio is about 10^3 for a technical (soda-lime) silicate melt under ambient water pressure (total water < 0.1 wt %), whereas it can reach 0.2 for geo-compositions for total water content of about 10 wt %.

If water speciation in metastable hydrous melt relaxes to the equilibrium value down to the glass transition, a three-component model can be used to reveal the individual contributions of OH groups, $\text{H}_2\text{O}(\text{m})$, and the “dry” network on T_g [40]. Expanding the database with viscosities of hydrous silicate melts and normalizing the T_{12} isokom to its value of the dry melt (set as 0.02 wt % total water), one finds that the data collapse on a master curve whose equation is [41]

$$\frac{T_{12}^{\text{hydrous}}}{T_{12}^{\text{dry}}} = \frac{1.01w_G + 0.22(Aw_{\text{OH}} + Bw_{\text{H}_2\text{O}(\text{m})})}{w_G + w_{\text{OH}} + w_{\text{H}_2\text{O}(\text{m})}}, \quad (22)$$

where $A = 30$, $B = 5$ and w_G , w_{OH} , and $w_{\text{H}_2\text{O}(\text{m})}$ are the weight fractions of the dry glass and water as OH groups and H_2O molecules, respectively (Figure 13).

6.4 Empirical Predictions from Composition

Predictions of viscosity as a function of temperature and glass composition are essential for industry. Present models are based on large data sources such as those provided by SciGlass and Interglad. They employ matrix algebra, nonlinear regressions, and structured chemical models, support multicomponent queries, and yield fast data presentations and viscosity predictions based on various property models.¹ The range of applicability of these models includes almost all known types of oxide glasses with a core competence in silicates. Other models have

Figure 13 Strongly depressing effects of water content on the viscosity of hydrous melts as represented by the $T_{12}(\text{hydrous})/T_{12}(\text{dry})$ ratio for synthetic and natural silicate melts. Dashed curve: predictions of Eq. (22) with $A = 30$ and $B = 5$.

been proposed [42–44]. Isokom curves can be generated with the help of glass data information systems.

7 Dependence on Time and Strain Rate

7.1 Time-Dependent Viscosity

After a sudden temperature change, a time-dependent viscosity is commonly observed in the GTR. In these experiments a glass specimen is first equilibrated at a temperature T_{f1} and then suddenly brought to the new temperature T_{f2} at which the viscosity is measured. Depending on whether $T_{f2} < T_{f1}$ or $T_{f2} > T_{f1}$, the viscosity increases or decreases with time toward the equilibrium value $\eta_0(T_{f2})$, respectively (Figure 14), in a time much longer than that needed to establish the new temperature and to relax stresses by viscous flow (see Section 7.3). Transient effects of viscosity are governed by the relaxation of the liquid toward its equilibrium structure at T_{f2} . The viscosity–time curve for $T_{f2} < T_{f1}$ and $T_{f2} > T_{f1}$ follows generally a stretched exponential dependence:

$$\frac{\eta(t) - \eta(t = \infty)}{\eta(t = 0) - \eta(t = \infty)} \bigg|_{T_{f2}} = 1 - \exp \left(- \frac{t}{\tau} \right)^n, \quad (23)$$

Figure 14 Increasingly slow viscosity relaxation with decreasing temperatures for soda-lime-silica glasses of different thermal histories after a sudden change in temperature from T_{f1} to T_{f2} .

where $\eta(t = 0)$ is the instantaneous (isostructural) viscosity, $\eta(t = \infty)$ the equilibrium viscosity η_0 , τ the structural relaxation time, and n the stretching exponent ($n < 1$).

7.2 Strain Rate-Dependent Viscosity

Another complication is the strain rate-dependent viscosity measured when the relaxation time for viscous flow approaches the inverse strain rate $1/\dot{\epsilon} = dt/d\epsilon$ of the deformation experiment. Under these extreme conditions, an apparent shear thinning is observed in experiments with deformation modes such as fiber elongation and cylinder compression. If the strain rate is normalized with the Maxwell stress relaxation time $\tau_\sigma = \eta_0/G_\infty$, the onset of the non-Newtonian flow is found at values three orders of magnitude lower, i.e. $\dot{\epsilon}\eta_0/G_\infty = 0.001$ (Figure 15). The flow curves and the apparent viscosity are influenced strongly by the dissipation of mechanical energy in the form of heat. Viscous heating and the temperature-induced decrease in viscosity have to be considered on the basis of an energy balance between heating and radiation effects, which depends mainly on the surface-to-volume ratio (A/V) of the deformed glass samples. For fibers, the change in temperature is negligible ($\Delta T \approx 0$), but for other geometries, viscous heating can exceed the heat loss at the surfaces ($\Delta T > 0$) and has therefore to be taken into account to make a clear distinction

Figure 15 Dependence of the normalized apparent viscosity η_{app}/η_0 on the normalized strain rate $\dot{\epsilon}\tau_\sigma$ for homogeneous soda-lime-silica glasses.

between the structural and thermal effects causing shear thinning.

Simmons et al. [45] showed that shear thinning can be described by a simple relationship between reduced viscosity and the normalized strain rate function $\dot{\epsilon}\tau_\sigma/\alpha$:

$$\frac{\eta_{app}}{\eta_0} = \frac{1}{1 + (\dot{\epsilon}\tau_\sigma/\alpha)}, \quad (24)$$

where $\eta_{app} = \sigma/\dot{\epsilon}$ is the apparent non-Newtonian viscosity and the factor α is the ratio between the maximum stress sustained by the liquid and the instantaneous shear modulus of the glass (σ_{limit}/G_∞). This equation is valid for stationary states when stress increases caused by increasing strain rates are counterbalanced by stress decreases induced by dissipative heat fluxes ($\Delta T \approx 0$). Under these conditions, the limiting viscosity η_∞ is assumed to approach zero as $\dot{\epsilon} \rightarrow \infty$. Yue and Brückner [46] have characterized in terms of the flow relaxation rate $\dot{\epsilon}_g$ the transition from the relaxed state of the Newtonian fluid to the unrelaxed flow of the highly stressed fluid. The latter is represented by the onset of a pseudo-Bingham flow in which the apparent viscosity is lower than in the Newtonian regime, but no longer strain rate dependent, i.e. $\eta_\infty > 0$. In this way, Yue and Brückner derived Eq. [46]:

$$\frac{\eta_{app}}{\eta_0} = \frac{\eta_\infty}{\eta_0} + \frac{\dot{\epsilon}_g}{\dot{\epsilon}} \left(1 - \frac{\eta_\infty}{\eta_0}\right) \left(1 - \exp\left(-\frac{\dot{\epsilon}}{\dot{\epsilon}_g}\right)\right). \quad (25)$$

Non-Newtonian flow in glass-forming liquids is assumed to originate in viscoelastic relaxation processes related to orientation-produced stresses. The observation of flow and frozen-in birefringence of fibers during drawing and after quenching, respectively, has been used to quantify the degree of structural orientation (strained network fragments) involved in shear thinning.

7.3 Non-Newtonian Flow and the Glass Transition Range

The transition from the relaxed state of the Newtonian fluid to the final brittle fracture via the unrelaxed non-Newtonian flow under high stress levels is closely related to the definition of the GTR. Assuming a Maxwell stress relaxation, one can replace the observation time t , which is not relevant to the glass transition induced by an external control parameter, i.e. the strain rate $t = 1/\dot{\epsilon}$, to define the GTR in terms of Reiner's rheologic Deborah number (De) as [47]:

$$GTR = De = \frac{\dot{\epsilon}\eta_0}{G_\infty} = 1. \quad (26)$$

Scaling of GTR with Eq. (26) reveals that the time needed to establish the equilibrium viscosity after a sudden temperature change is related to $De = 10^{-2}$, whereas the onset of shear thinning takes place at $De = 10^{-3}$ (Figure 16). Both results indicate that stress relaxation is too fast to cause transient effects and strain rate-dependent viscosity. But they emphasize that the characteristic times involved in structural relaxation, which are related to long-range cooperative rearrangements of the equilibrium structure, are slower by a factor of up to 1000 than for relaxing stress through shorter structural pathways.

The melt fracture is closely related to $De = 1$ if one considers glass geometries of large A/V ratio, such as double-ring bended thin glass panes. The fracture of the melt is related to the limiting elastic response of the strained bonds under stresses exceeding a critical level. If viscous heating is involved, fracturing events can already occur at lower strain rates ($De = 10^{-1.5} - 10^{-2}$) through formation of temperature gradients and, therefore, of stress concentration in the less strained parts of the sample.

8 Dependence on Microstructure

8.1 Heterogeneous Melts

The presence of a microstructure leads to an increasingly complex viscous flow as a result of controlled phase formation (glass-ceramic and foam-glass products), of batch-to-melt reactions when granular raw materials

Figure 16 From brittle fracture to shear thinning: dependence of viscosity on time (strain rate) for homogeneous soda-lime-silica glasses. Solid lines: visual guides; dashed lines: liquid-to-solid transitions based on stress relaxation (Maxwell model with $G_{\infty} \approx 30$ GPa) and normalized to Reiner's Deborah number definition, Eq. (26). Newtonian flow expressed by the time- and strain rate-independent viscosity η_0 requiring structural relaxation of the liquid, i.e. two to three orders of magnitude longer times than Maxwell stress relaxation, $De = 10^{-2} - 10^{-3}$. For soda-lime-silica glass, $\eta_0(10^2 \text{ seconds}) = 10^{9.5} - 10^{10.5} \text{ Pa}\cdot\text{s}$.

react to form the bubbly unfined (“fresh”) melt, or of uncontrolled devitrification, liquid unmixing of degassing in industrial or geological contexts. Because of the metastability of supercooled liquids, the fractions of precipitated crystals and secondary liquids increase in general with time below the liquidus or critical temperature, respectively. A time-dependent rheology then is observed not only because of the physical effects resulting from the coexistence of two phases but also because the chemical composition of the residual melt changes continuously.

At temperatures close to the glass transition, the involved transformation kinetics are generally slow, which enables rheometric measurements to be made under quasi-stationary microstructural conditions, i.e. at constant fractions of secondary crystals, bubbles, and liquids, which are dispersed in the volume of the residual liquid matrix ([48, 49] and other early papers having relied on this assumption). Under these conditions, heterogeneous liquids can be treated as suspensions. One can then define the suspension-to-matrix ratio of the viscosity by

$$\eta_{\text{rel}} = \frac{\eta_{\text{susp}}}{\eta_0}, \quad (27)$$

where η_{rel} is the relative viscosity, η_{susp} the effective viscosity of the suspension, and η_0 the Newtonian viscosity of the liquid continuous matrix.

8.2 Crystal-Bearing Melts

The laminar flow of liquids is generally hindered by the presence of rigid inclusions, which cause an increase in the flow resistance of the suspension, i.e. $\eta_{\text{rel}} > 1$. The increase depends on the volume fraction of rigid crystals ϕ and their size distribution and shape. For dilute ($\phi < 0.03$) monodispersed suspensions of spheres, Einstein [50] derived the linear equation ($\eta_{\text{rel}} = 1 + B_E \phi$ with $B_E = 5/2$). The factor B_E is the intrinsic viscosity or Einstein coefficient for which the values proposed for different systems range from $3/2$ to $10/2$. For a non-dilute suspension, interactions between crystals must be taken into account, which leads to a stronger (exponential or power law) dependence on crystal fraction. At a critical volume fraction ϕ_{max} , the crossover between liquid-like and solid-like rheology is observed. For $\phi < \phi_{\text{max}}$, the relative viscosity is frequently described by the empirical generalization:

$$\eta_{\text{rel}} = (1 - B_E \phi)^n, \quad (28)$$

where $B_E = 1/\phi_{\text{max}}$ and n are adjustable parameters. For close, random, and loose-packed monodispersed spheres, $\phi_{\text{max}} = 0.74, 0.64-0.62$, and $0.6-0.56$ are used, respectively. For random packing of non-spherical crystals (bars, needles) of aspect ratio $\alpha > 10$ ($\alpha = l/d$ with l = length and d = diameter), the equation $\phi_{\text{max}} = 5/\alpha$ holds [51]. For the exponent n , values in the range $-5/2 \leq n \leq -3/2$ are reported such as $n = -5/2$ [52], $n = -4/2$ [53], and $n = -B_E \phi_{\text{max}}$ [54].

For shearing semi-concentrated suspensions with $\phi > 0.3$, the dependences of the relative viscosity on both yield stress and strain rate become evident. The non-Newtonian flow is observed to be of shear thinning type (crystal alignment for non-spherical crystals). Phenomenological equations of the relative viscosity have been proposed to bypass the viscosity divergence of Eq. (28) as $\phi \rightarrow \phi_{\text{max}}$ and to bridge the viscous flow of suspensions with the creep of polycrystalline solids. For a constant strain rate, one finds [55]

$$\eta_{\text{rel}} = \left\{ 1 - A \operatorname{erf} \left(\frac{\sqrt{\pi}}{2} \phi \left[1 + \frac{B}{(1-\phi)^C} \right] \right) \right\}^{-B_E/A} \quad (29)$$

with A, B, C = adjustable parameters.

Experimental data show that for the overall evolution of the relative viscosity with the dispersed volume fraction of rigid crystals, a sigmoidal-shaped increase of up to eight orders of magnitude becomes evident (Figure 17). Its point of inflection, which marks the crossover between liquid-like and solid-like rheology, seems to be specific for each melt and shifts with the aspect ratio and type of packing of the dispersed crystals.

8.3 Bubbly Melts and Emulsions

In contrast to rigid crystal inclusions, the deformability of gas bubbles and liquid droplets (immiscible melts) has to be considered if the deforming (viscosity) forces exceed the retaining (interfacial energy) forces. The equilibrium deformation of a gas bubble and liquid droplet is, therefore, a function of the capillary number:

$$Ca = \frac{\eta_0 r \dot{\epsilon}}{\gamma}, \quad (30)$$

where r is the radius of the bubble or liquid droplet and γ the liquid–gas or liquid–liquid interfacial energy. For bubbly melts and emulsions subjected to steady shear under $Ca > 1$, spherical bubbles (droplets) of volume fraction ϕ will deform, and the apparent viscosity of the melt is predicted to decrease. In contrast, shearing under $Ca < 1$ allows bubbles/droplets to keep their spherical shape and leads to an increase of the apparent viscosity. Empirical equations have been proposed for demixed and bubbly melts of the same type as Eq. (28):

$$\eta_{\text{rel}} = (1 - B_E \phi)^n, \quad (31)$$

where B_E and n are adjustable parameters. Depending on rheometric regime with $Ca > 1$ vs. $Ca < 1$ and the fraction of suspended bubbles (liquids), i.e. dilute vs. semi-concentrated, different values of B_E and n in Eq. (31) have been proposed. In particular for dilute emulsions, linear equations ($n=1$) are proposed such as $B_E=1$ for emulsions under $Ca < 1$ [56], whereas for semi-concentrated emulsions nonlinear equations with $n = -5/2$ and ($B_E=1$ for polydispersed emulsions and $B_E=1.35$ for monodispersed emulsions) are used to fit apparent viscosity data under $Ca < 1$.

Allowing bubble deformation ($Ca > 1$) fits to the experimental data for bubbly silicate melts with volume fractions up to $\approx 62\%$ can be made with $B_E=1$ and $5/3 \leq n \leq 15/3$ (Figure 17). These data show that deformable bubbles can decrease the relative viscosity by up to two orders of magnitude, which is much smaller than the increase caused by rigid crystals.

Figure 17 Contrasting effects of the volume fractions of rigid solid inclusions (ϕ) and deformable gas bubbles (ϕ) on the relative viscosity η_{rel} of heterogeneous melts. Crystal-bearing melts, solid line: Eq. (28) for loose-packed monodispersed spheres with $n = -5/2$ and $\phi_{\text{max}} = 0.58$. Bubble-bearing melts, solid line: Eq. (31) for $B_E = 1$ and $n = 5/2$.

9 Perspectives

Viscosity control is essential for glass melting, forming, and cooling, which requires detailed knowledge of the manner in which the rheology depends on temperature and chemical composition and, when inclusions are present in the melt, on their nature and volume fraction. In industry, models have thus been developed for the accurate description of viscosity–composition–temperature relationships from comprehensive databases. In this area, progress will result from industrial and academic research since simulation of dynamic processes is gaining more and more in importance for designing glasses of desired viscous properties. Besides glass industry, geosciences have become a key driver for explaining viscous phenomena with respect to heterogeneity and volatile elements. This expertise will help not only to understand batch and fining processes of glass manufacturing but also engineering of highly viscous composite phases such as glass–polymer hybrids for dental applications and partially crystallized seals for high-temperature fuel cells. From a theoretical standpoint, however, much work remains to be done to understand viscosity at a really fundamental level. The reason, of course, is that viscosity is closely related to the glass transition, which remains itself an elusive phase transformation (Chapter 3.2).

Appendix

A.1 Supplementary Information

Table 2 From Douglas et al. (1965), Gent (1960), Hagy (1963), Trouton and Andrews (1904).

Figure 3. Division in three viscosity ranges after Nemilov (1992). Data from Sipp et al. (1997, SLS-1), Zeitka and Deubener (2004, SLS-2), De Bast and Gilard (1965, SLS-3), Meinhard et al. (2001, SLS-4), Mazurin et al. (1979, SLS-5), Gerard and Troussard (1951, SLS-6), Jones (1944, SLS-7), and Blaimont et al. (1951, SLS-8).

Figure 4. Data from Martin and Angell (1986, P_2O_5), Urbain et al. (1982, SiO_2), Fontana and Plummer (1966, GeO_2), Napolitano et al. (1965, B_2O_3), Macedo and Napolitano (1968, B_2O_3), Böse et al. (2001, soda-lime-silica, Schott code AR 8350; lead silicate, Schott code LLF1; borosilicate, Schott code 8486), Masuhr et al. (1999, $Zr_{41.2}Ti_{13.8}Cu_{12.5}Ni_{10.0}Be_{22.5}$ – Vitleroy 1), Schröter and Donth (2000, glycerol), Weiler et al. (1969, K, Ca-nitrate), Tweer et al. (1971, K, Ca-nitrate), and Greet and Turnbull (1967, o-terphenyl).

Figure 5. Data sources: E-glass (1) of composition 56.51 SiO_2 , 14.3 Al_2O_3 , 6.40 B_2O_3 , 18.36 CaO , 2.65 MgO , 0.55 FeO , 0.45 Na_2O , 0.35 K_2O , 0.12 TiO_2 (wt %), and 15.91 mol/kg glass with the AG parameter (Eq. 5.6): $A_6 = -3.51$, $B_6 = 2\,670\,200\,J/kg$, $S^{conf}(T_g) = 197.6\,J/kg/K$, $a = 290.02\,J/kg/K$, $b = 0$, $T_g = 996\,K$ (Sipp et al., 1997); E-glass (2): 53.6 SiO_2 , 14.6 Al_2O_3 , 0.3 Fe_2O_3 , 23.5 CaO , 6.3 B_2O_3 , 0.9 Na_2O , 0.7 F_2 (wt %) and 15.81 mol/kg glass with the AG parameter of Eq. (18): $A_6 = -2.65$, $B_6 = 1\,723\,380\,J/kg$, $S^{conf}(T_g) = 126.3\,J/kg/K$, $a = 315\,J/kg/K$, $b = 0$, $T_g = 952\,K$ (Deubener et al., 2008)

Figure 8. Data sources as in Figure 4. Calorimetric T_g ($\tau = 10^2$ seconds) and T_c temperatures are collected from Martin and Angell (1986) and Masuhr et al. (1999) and the compilations of Böhmer et al. (1993), Rössler and Sokolov (1996), [26], Hess et al. (1996), Richert and Angell (1998, [25]) and obtained by fitting the general dependence (indicated by a star in the legend).

Figure 9. Viscosity data from various authors (SciGlass query). Immiscibility dome as calculated from Haller et al. (1974) model with $\Delta S/R = 0.3$, a critical temperature of 1110 K and $(SiO_2)_8$ and $Na_2O \cdot 3SiO_2$ virtual end members.

Figure 10. Viscosity data from various authors (SciGlass query).

Figure 11. Data are from the collections of Eisenberg et al. (1966, [30]), Striepe and Deubener (2012), and Rodrigues and Wondraczek (2014). Glass transition temperature is used when viscosities not reported. For $H(PO_3)$ z/R_{M-O} is set as zero ($T_{12} = 263\,K$) and linear average of z/R_{M-O} is assumed for binary metal mixtures.

Figure 12. Data from Riebling (1966, inverted triangle), Cranmer and Uhlmann (1981, diamond), Toplis et al.

(1997a, box), Toplis et al. (1997b, circle) and Webb et al. (2004, triangle).

Figure 13. Data from the collection of Deubener et al. (2003, [41]) and from Del Gaudio et al. (2007). For hydrous sodium silicate glasses, data of the gel-to-glass transition are included. Glass transition temperature is used if viscosities are not reported. Dashed line gives the prediction of Eq. (22) with $A = 30$ and $B = 5$.

Figure 14. Data collected from Sipp et al. (1997, SLS-1) and Lillie (1933, SLS-2).

Figure 15. Data collected from Simmons et al. (1982, SLS-1 [45]), Yue and Brückner (1994, SLS-2 [46]), Yue and Brückner (1994, SLS-2), and Thies and Deubener (2002, SLS-3).

Figure 16. Data collected for the time to establish equal viscosity in glasses of high and low fictive temperatures (Figure 14) from Lillie (1933, SLS-2, fiber elongation) and Sipp et al. (1997, SLS-1, compression experiments) and for the strain rate to initiate shear thinning from Manns and Brückner (1985, SLS-4, cylinder compression), Simmons et al. (1988, SLS-3, fiber elongation, cone-cup shear), and Yue and Brückner (1994, SLS-5, cylinder compression) as well as for the critical rate to brittle fracture of double-ring bended sheet glasses (SLS-4, Manns and Brückner, 1983).

Figure 17. Crystal-bearing melts: data from Vona (2011), Caricchi et al. (2007), Sato (2005), Lejeune and Richet (1995, [48]), and Deubener (1994). Bubble-bearing melts: Data from Thies and Deubener (2002), Stein and Spera (2002), Manga and Loewenberg (2001), Lejeune et al. (1999, [49]), Sura and Panda (1990), and Ducamp and Raj (1989).

Ionic and Electronic Transport

Jean-Louis Souquet

Laboratoire d'Electrochimie et de Physicochimie des Matériaux et des Interfaces, PHEMMA, Saint Martin d'Hères Cedex, France

1 Introduction

Electrical transport in glasses and glass-forming melts is caused by the displacement of mobile charged species, namely, ions and electrons. The existence of ionic conduction in glasses was proved in 1884 by Emil Warburg (1846–1931) [1] who described Na^+ transfer through a thin glass membrane separating two sodium amalgams. Since then, the phenomenon has been put to innumerable uses, thanks in particular to the possibility of enhancing conductivity through optimization of the chemical composition of the material. To give a single example, substitution of sulfur for oxygen in lithium-bearing glasses causes the conductivity to reach a value of about $10^{-3} \text{ S cm}^{-1}$ at room temperature, which is similar to those of liquid electrolyte solutions, whence the use of these materials as electrolytes in secondary solid-state lithium cells ([2, 3], Chapter 9.5).

In a general way, ionic conductivities vary with temperature according to Arrhenius laws up to the glass transition and show the highest values for glasses and melts bearing singly charged cations such as Li^+ , Na^+ , or Ag^+ . Since ionic transport makes it possible to modify the chemical composition of the glass surface, it is, for instance, used industrially to strengthen glass by ion stuffing (see Chapter 3.12) or to obtain index gradients in optical guides. In addition, ion conductive glasses are currently used as active membranes for electrochemical devices, as pH or ion selective electrodes (Chapter 5.8), whereas ionic conduction also plays a fundamental role in redox reactions in melts (Chapter 5.6, [4]). As will be first described in this chapter, a comprehensive

understanding of ionic transport associates concepts already developed in the field of ionic crystals, electrolytic solutions, molten salts, and thermodynamics.

When transition elements are present in at least two redox states, electrical conduction can also take place in a large variety of glasses by tunneling electron transfer between localized donor and acceptor states energetically located between the valence and conduction bands. Although electronic conduction also follows Arrhenius laws below the glass transition, its mechanisms are thus completely different from those of ionic transport. Following the pioneering approach developed by Mott [5] in the 1960s, electronically conductive glasses have been studied for more than 50 years. In the last two decades, they have even been more extensively investigated than ionic conductive glasses because of their high-tech applications. For instance, Se or As–Se photoconductive chalcogenide glasses have enabled the photocopying process to be developed, whereas electronic conduction in amorphous hydrogenated silicon, a-Si:H, has boosted production of low-cost solar cells [6]. In addition, electronically conductive amorphous phases of transition metal oxides such as WO_3 , MoO_3 , and glassy systems containing V, Fe, Mo, or Cu oxides associated with glass formers such as SiO_2 , P_2O_5 , and TeO_2 have been studied for applications as electrochromic coating for “smart windows” or electrode materials in lithium batteries.

If subjected to a high electric field, electronically conductive glasses may eventually switch reversibly from low to high conductivity, a property that is now exploited in electrical memory devices for information storage [7]. As will be seen in the second part of this chapter, theoretical studies of electronic conductivity, as well as the corresponding terminology, derive from usual concepts of solid-state physics. This is why electronic conductive glasses have been most studied by the physics community.

2 Ionic Conductivity and Diffusion

2.1 Experimental Determination

The ionic conductivity, σ_i , is readily determined from the electrical resistance R_i of a sample between two parallel metallic electrodes of surface S mutually separated by a distance d : $\sigma_i = \frac{1}{R_i} \times \frac{d}{S}$.

From an experimental point of view, the major difficulty arises from the fact that the sample is an ionic conductor, whereas the electrodes are electronic conductors. Hence, there is an irreversible energy loss caused by charge transfer at the sample/electrode interface, which is represented by a resistance R_{tr} in series with the sample resistance. To separate these two resistances, the usual technique is to perform ac impedance measurements in the 10 Hz to 1 MHz range. A representation of the impedance Z^* in the complex plane then enables one to separate the bulk response from that of the glass/electrode interface and to determine accurately R_b and σ_i .

If no transfer resistance were existing at the glass/electrode interface, the electrical conductivity could be measured from direct current (dc) measurements. For this reason σ_i is often ambiguously called dc conductivity (σ_{dc}) even though it is actually determined from ac measurements. As usually expressed in $S\text{ cm}^{-1}$ or $\Omega^{-1}\text{ cm}^{-1}$, the ionic conductivity of window glass typically ranges from 10^{-15} to $10^{-13}\text{ S cm}^{-1}$ at room temperature, which is why glasses are usually considered as insulators at room temperature. Such low values are more conveniently expressed in terms of resistivity $\rho = 1/\sigma$.

The highest ionic conductivities are observed when monovalent cations such as alkalis are present in the glass. Compared with that of alkalis, the contribution of cations having a higher positive charge, such as Ca^{2+} or Pb^{2+} , is much lower because, at a similar cation concentration, they are more tightly bonded to the anionic framework, causing their room-temperature conductivity to be lower by five to eight orders of magnitude. Consequently, the majority of conductivity data and theoretical approaches deal with monovalent cations.

The ionic conductivity, σ_i , and the diffusion coefficient, D_i , of a monovalent cation are linked by the Nernst-Einstein proportionality relationship:

$$\sigma_i = \frac{xe^2 D_i}{k_B T}, \quad (1)$$

in which x is the cation concentration, T is the absolute temperature, and e and k_B are the electron charge and Boltzmann constant. This relationship simply assumes that ionic transport and diffusion are governed by the same mechanism, whatever the “driving force,” electric field, or concentration gradient may be.

2.2 Temperature Dependence of Ionic Conductivity

Below the glass transition, the ionic conductivity increases exponentially with temperature to follow an Arrhenius law:

$$\sigma_i = \frac{A_i}{T} \exp\left(-\frac{E_a}{k_B T}\right), \quad (2)$$

where E_a is the activation energy, which usually ranges from 0.5 to 1.5 eV (i.e. approximately 50 and 150 kJ mol^{-1}), and where the constant A_i does not significantly depend on glass composition with values of 10^4 – 10^5 K S cm^{-1} . This feature means that conductivities extrapolated at infinite temperature would converge to a common value. The conductivity differences of about 10 orders of magnitude observed at room temperature (typically from 10^{-17} to 10^{-7} S cm^{-1}) are thus due to variations in the $E_a/k_B T$ rather than to the pre-exponential A_i/T term. For alkali and alkaline earth, conductive glasses, E_a ranges between 0.6 to 1 eV and between 1.3 and 1.7 eV, respectively [8]. Up to the glass transition these variations of A_i/T over intervals of a few hundred degrees are actually small enough that one generally prefers the alternate equation

$$\sigma_i = \sigma_{0i} \exp\left(-\frac{E_a}{k_B T}\right). \quad (3)$$

Above the glass transition, the ionic conductivity dependence with temperature is no more Arrhenian and increases faster with temperature. Like those of viscosity, however, its variations cannot be represented by Eq. (2) or (3) as illustrated in Figure 1 for two sodium

Figure 1 Contrast between the Arrhenian and non-Arrhenian regimes of the low- and high-temperature ionic conductivity for two glass-forming melts with 20, 25, and 55 (SBN20) and 30, 22, and 48 (SBN30) mol % Na_2O , B_2O_3 , and SiO_2 , respectively, illustrating how cooperative motion of the borosilicate chains enhance the mobility of charge carriers.

Figure 2 Composition dependence of the ionic conductivity in alkali silicate glasses. (a) Effect of the ($\text{Na}_2\text{O}, \text{SiO}_2$) substitution at 100 °C. (b) Mixed alkali effect at temperatures from 150 to 300 °C resulting from (Na, Li) substitution in disilicate glasses.

borosilicate glass forming melts [9]. Above 1300 °C, glass-forming melts even reach very high ionic conductivities of about $10^{-2} \text{ S cm}^{-1}$, which are similar to those found for strong aqueous electrolyte solutions. As a matter of fact, it is this ionic-resistor character that makes it possible to increase (boost) the temperature of a glass-forming melt by Joule heating with immersed molybdenum electrodes (Chapter 9.7).

2.3 Composition Dependence of Ionic Conductivity

Ionic transport is highly sensitive not only to temperature but also to the nature and concentration, x , of the moving cations. In alkali silicates, doubling x , for instance, induces a 10- to 100-fold increase in conductivity. This sensitivity to chemical composition is spectacularly illustrated by the mixed alkali effect (Chapter 4.6, [10, 11]). At a constant concentration of alkali cations, the progressive substitution of an alkali by another results in a marked decrease in the ionic conductivity, compared with that of glasses containing only one alkali, which becomes even stronger when the temperature decreases (Figure 2).

3 Ionic Transport Mechanisms

3.1 General Features

Regardless of any particular mechanism, electrical transport can be expressed as the product of the concentration

of effective charge carriers, x_e , their mobility, μ_i , and electrical charge, e_i . In the simplest case of a positively charged monovalent cation, the ionic conductivity, σ_i , then is

$$\sigma_i = e \cdot x_e \cdot \mu_i. \quad (4)$$

In electrolyte solutions or ionic conductive crystals, the concentration x_e of effective charge carriers is the mean concentration of the ions actually moving. Usually, it is expressed as the number of charge carriers by cm^{-3} so that ion mobilities are reported in $\text{cm}^2 \text{ s}^{-1} \text{ V}^{-1}$, which represents the speed of charge carriers in cm s^{-1} when subjected to an electric field of 1 V cm^{-1} . In any case, it is generally admitted that $x_e \ll x$, which does not mean that some cations will never move, but only that, statistically, a small fraction of all cations move at any given time. At equilibrium, however, a continuous exchange takes place such that each cation is alternatively an effective charge carrier or is trapped in a fixed position (Chapter 4.6). Below the glass transition, alkali cations move in a frozen network. Ionic transport in glasses thus is usually interpreted in terms of the vacancy or indirect interstitial mechanisms described for ionic crystals. Above the glass transition, in contrast, cations no longer move in a frozen network. The rearranging structural entities of the melt participate in cation displacements so that conduction mechanism become comparable to those of molten salts or ionic polymers. The various mechanisms proposed for these low- and high-temperature regimes will now be described in some detail.

3.2 Ionic Transport Below the Glass Transition: The Ionic Crystal Formalism

3.2.1 Anderson–Stuart Model: A Vacancy Mechanism

This model [12] mainly serves to estimate the activation energy for ionic migration, E_a , from classical electrostatic and elasticity theories. Its mechanism is similar to that of vacancy formation because it assumes the presence of a large number of available cation sites, but does not distinguish between bridging and nonbridging oxygens and posits that all the constituents of the material are in an ionic form. Then the basic idea is that an ion makes a simple hop from one site to another, passing through a “doorway” that opens to the size of the ion as it passes through. As a result, the activation energy E_a is the sum of two terms, the electrostatic binding energy, E_B , and the strain energy, E_S , required to move an ion from one site to another. Because the anion–cation distance increases with cation size, the ionic binding energy correlatively decreases and the strain energy increases. In the expression of the activation energy $E_a = E_B + E_S$, the two terms compete, and for a given glass structure, the activation energy is expected to present a minimum as a function of the cation size. For alkali and alkaline earth silicate glasses, this minimum is found for Na^+ and Sr^{2+} , respectively. Despite its simplicity, this model yields the right orders of magnitude for activation energies and their dependence on cation size.

3.2.2 An Improved Vacancy Mechanism: The Dynamic Structure Model

In single M^+ cation conductive glasses, the model proposed by Bunde, Ingram, and Maass [13] relates the ionic conductivity and its activation energy to the concentration of the network modifier oxide, M_2O . When trapped in a regular cationic site, an M^+ cation induces a local deformation of the surrounding glass network as a result of its positive charge and size. To some extent, the cation can be compared with a polaron in an ionic crystal, in which the local structure adapts to a trapped electron. When the M^+ cation jumps out of its site, this associated local deformation relaxes toward a new equilibrium state, preserving the “memory” of this local deformation for some time. The moving M^+ cation may then either create a new cationic site adapted to its charge and radius or jump into a relaxing empty cationic site. Owing to the energy cost required to create a new local reorganization, the activation energy for the jump is higher in the first event and makes this first step less probable than the second.

With Monte Carlo computational simulations (Chapter 2.8), one can show that cationic sites tend to form fluctuating clusters whose size increases as a function of the M_2O concentration or temperature. These

clusters percolate through cationic pathways, enabling cations to migrate in the glass. The ionic conductivity calculated by this procedure accounts for the strong dependence of ionic conductivity on composition (Figure 2a) and reproduces the experimentally observed logarithmic decrease of E_a with alkali oxide content. Such a model also yields a satisfactory interpretation of the mixed alkali effect (Figure 2b) if extended to two different alkali charge carriers, each generating a different cationic site.

3.2.3 Charles Model: An Interstitial Pair Mechanism

This mechanism assumes that the charge carriers are cation pairs composed of two alkalis sharing the same equilibrium site [14]. In an oxide glass, an equilibrium site could be a negatively charged nonbridging oxygen bonded to a cation. Such a neutral association is all the more stable that the relative dielectric constant ϵ_r of an oxide glass is low, ranging typically between 5 and 15 [8]. Nevertheless, thermal vibrations allow for partial dissociation so that some alkali cations escape from the electrostatic attraction of their nonbridging oxygens and jump into the potential well of a neighboring oxygen already occupied by another alkali cation. The cationic pair thus created forms a positive charge carrier (Figure 3a), which can be considered as a defect from an electrostatic standpoint. Being unstable, the cationic pair expels an alkali to a neighboring nonbridging oxygen already associated with another alkali cation, and so on. Each time a cation pair is formed it migrates along the electric field from one nonbridging oxygen to another (Figure 3b). Implying an exchange in coordination number between two neighboring nonbridging oxygens, this mechanism can be compared to the transfer of protons in water from a H_3O^+ hydronium ion to a H_2O molecule by a mechanism originally described by Theodor von Grotthuss (1785–1822) [15].

3.2.4 Mechanisms Inferred from Diffusion Measurements

For an ionic crystal, and also for a glass, the diffusion coefficient of an element, D_i^* , determined by radiotracer experiments is slightly lower than D_i , deduced with the Nernst–Einstein equation (1) from conductivity data. This difference is expressed by $D_i^* = H_R D_i$, where H_R is the Haven ratio. In a crystalline ionic conductor, in which ions follow a random walk as in a direct interstitial process, H_R is expected to be unity. If some jumps are precluded after a given jump, the Haven ratio depends on the number Z of neighboring sites, being approximated by $H_R = [1 - 2/Z]$ for a vacancy mechanism and by $H_R = [1 - (1/Z)]$ for an indirect interstitial process. Because Z depends on crystal structure, a determination

Figure 3 Possible ionic transport mechanisms. (a) Formation of an interstitial pair by an activated process. (b) Interstitial pair migration by an activated mechanism below the glass transition. (c) Interstitial pair migration by an entropic mechanism involving cooperative chain movements above the glass transition.

of H_R enables these transport mechanism to be distinguished.

In a glass, the local structure, and hence Z , is not well defined, and the determination of H_R is less conclusive. For silicate glasses with high Na^+ contents, the values found for H_R range from 0.44 to 0.55 and tend toward unity at low contents [16, 17]. From Charles model [14], one assumes that the cationic interstitial sites consist of many equivalent positions around a nonbridging oxygen already associated with another cation. At very low Na^+ concentrations, diffusive motion would occur by a direct interstitial mechanism between different nonbridging oxygens.

3.2.5 More About the Ionic Crystal Formalism

Starting from the interstitial pair model, one readily extends the classical defect model to glasses [18] and, in this way, accounts for the Arrhenian variations of ionic transport, i.e. Eq. (2) or (3). Assuming that charge carriers are formed in glasses through an activated process, one expresses their concentration as

$$x_e = x \exp \left(- \frac{\Delta G_f}{2k_B T} \right), \quad (5)$$

where $\Delta G_f = \Delta H_f - T\Delta S_f$ is the Gibbs free energy associated with the simultaneous formation of an interstitial pair and a cationic “vacancy” and ΔH_f and ΔS_f are their formation enthalpy and entropy, respectively. As for the factor 2 in the exponent, it expresses the fact that the

process generates two charged species, a charge carrier and its vacant site, both in the same amounts.

Using the Nernst–Einstein equation (1), one expresses the mobility of the charge carriers as a function of their diffusion coefficients D_i and then as a function of their characteristic attempt frequency, ν , and jump distance, λ :

$$\mu_i = \frac{eD_i}{k_B T} = \frac{e\lambda^2\nu}{6k_B T} \Omega, \quad (6)$$

where Ω is the probability of a successful jump. For a thermally activated mechanism, $\Omega = \Omega_1$ with a value that is a function of the Gibbs free energy required for migration, ΔG_m :

$$\Omega = \Omega_1 = \exp \left(- \frac{\Delta G_m}{k_B T} \right). \quad (7)$$

Finally, the following expression can be proposed for the cationic conductivity:

$$\sigma_i = ex_e\mu_i = x \frac{e^2\lambda^2\nu}{6k_B T} \exp \left(- \frac{\Delta G_f/2 + \Delta G_m}{k_B T} \right), \quad (8)$$

or, after separation of the enthalpic and entropic terms:

$$\sigma_i = x \frac{e^2\lambda^2\nu}{6k_B T} \exp \left(\frac{\Delta S_f/2 + \Delta S_m}{k_B} \right) \exp \left(- \frac{\Delta H_f/2 + \Delta H_m}{k_B T} \right). \quad (9)$$

Because this relationship is of the same form as the experimentally observed Arrhenius law, identification with Eq. (2) yields the parameter E_A as

$$E_A = \Delta H_f/2 + \Delta H_m, \quad (10)$$

and the temperature-independent term A_i as

$$A_i = x \frac{e^2\lambda^2\nu}{6k_B} \exp \left(\frac{\Delta S_f/2 + \Delta S_m}{k_B} \right). \quad (11)$$

The pre-exponential term $xe^2\lambda^2\nu/6k_B$ can be assessed numerically from realistic values of density and far infrared data, namely, $x = 10^{22}$ ions cm^{-3} , $\lambda = \sqrt[3]{1/x}$, and $\nu = 10^{13}$ Hz, yielding $A_i \approx 10^5$ K S cm^{-1} , which is close to typical experimental values. Consequently, either the exponential term in Eq. (11) is close to unity or the entropy terms are very low compared with k_B . This means that charge carrier formation and migration do not induce a significant change in the local order, as it would be expected from a rigid macromolecular network below the glass transition temperature.

3.2.6 Ionic Transport and Pressure

Most ionic conductivity data are presented as a function of composition and temperature. Complementary information can be deduced from the pressure dependence

of the conductivity variations as measured under isostatic conditions when a glass sample is immersed in an insulating oil between 1 and 5000 bar [19, 20]. A significant decrease in ionic conductivity is observed, which can be converted into an activation volume.

Because $xe^2\lambda^2\nu$ can be considered constant, one determines the pressure dependence of the conductivity by differentiation of Eq. (8):

$$\left(\frac{\partial \ln \sigma_i}{\partial P}\right)_T = -\frac{1}{k_B T} \left(\frac{\partial(\Delta G_f/2 + \Delta G_m)}{\partial P}\right)_T. \quad (12)$$

Then, since $d\Delta G = \Delta V dP - \Delta S dT$, Eq. (12) can be rewritten as

$$\Delta V_f/2 + \Delta V_m = \Delta V_a = -k_B T \left(\frac{\partial \ln \sigma_i}{\partial P}\right)_T, \quad (13)$$

where ΔV_a is an activation volume, i.e. the local variation of volume necessary for the formation and displacement of a charge carrier. Experimentally, one finds that the activation volume is close to the estimated ionic volume calculated from the Goldschmidt radius of the positive cation causing ionic transport.

3.2.7 The Weak Electrolyte Model

Ravaine and Souquet [21] extended the concept of weak electrolyte solutions to glassy electrolytes in order to interpret the huge variations observed in ionic conductivity as a function of the total alkali ion concentration (Figure 2a). Basically, the charge carrier mobility μ_i is expected to remain constant at a constant temperature for a given glass former. The number of charge carriers would then result from the partial dissociation of the modifier in a solvent of low dielectric constant, which is the glass former. In the simple case of a M_2O - SiO_2 binary glass, where M is an alkali cation, the dissociation equilibrium is

with Kröger–Vink notation, which allows for clearer identification of the species, assuming an interstitial pair formation ($2M^*$) as a charge carrier, which could be a nonbridging oxygen associated to two alkali cations (Figure 3a):

The equilibrium constant associated with the dissociation reaction (14) is

$$K = \exp\left(\frac{-\Delta G_f^0}{k_B T}\right), \quad (15)$$

where ΔG_f^0 is the standard Gibbs free energy of dissociation relevant to a specific composition. For high values of

ΔG_f^0 , K is very low so that there are far fewer effective charge carriers than alkali cations. At a constant temperature, but for different M_2O amounts, the number of effective charge carriers can be written as

$$x_e = x \exp\left(\frac{\Delta G_f^0 + \Delta \bar{G}_{M_2O}}{2k_B T}\right), \quad (16)$$

where $\Delta \bar{G}_{M_2O}$ is the chemical potential of M_2O in the chosen reference state and in the glass under study. Finally, since the mobility term is considered constant, the variations in ionic conductivity with composition follow the variations in the partial free energy of the alkali oxide, according to

$$\log \sigma_i \propto \log x_e \propto \frac{\Delta \bar{G}_{M_2O}}{2k_B T}. \quad (17)$$

Thus, the considerable variations observed in conductivity are representative of the significant variations with composition of the chemical potential of the alkali oxide. In a further step, one can interpret these variations by applying to glasses usual thermodynamic formalisms such as the regular or quasi-chemical models (Chapter 5.3).

4 Ionic Transport Above the Glass Transition: An Entropic Mechanism

As already noted, above the glass transition the rearranging structural entities of the melt participate in the cationic displacement so that conduction mechanisms become comparable to those in molten salts or ionic polymers [22, 23]. Under these circumstances, the ionic conductivity of a melt is higher than the values extrapolated from the Arrhenius law for the glass. This difference points to the existence of other modes of transport in addition to the aforementioned activated migration mechanism. This high-temperature process, represented schematically in Figure 3c, is associated with the local movement of the network-forming macromolecular chains. In this process, the transfer of the interstitial pair is no longer “drawn out” from the mean thermal energy $k_B T$ but from the available configurational entropy [24] associated with the chain movements.

In a supercooled glass-forming liquid, this configurational entropy decreases with temperature and would disappear at the *ideal* glass transition temperature, T_0 (Chapter 3.3, [25, 26]). As estimated by extrapolation from the thermodynamic or dynamic characteristics of the supercooled liquid, this temperature is much lower than the glass transition temperature as, for instance, determined by differential scanning calorimetry ($T_g \cong 1.3 T_0$).

The probability of a charge carrier transfer by such an entropic process depends on the available configurational entropy, and consequently on T_0 , and is expressed by

$$\Omega_2 = \exp \left(- \frac{B}{k_B(T - T_0)} \right), \quad (18)$$

where B is an energy dimension constant.

According to the present model, the moving species is in this case an interstitial pair transferred from one non-bridging oxygen site to another, allowing for charge transfer in the glass network. Above T_0 , the charge transfer may occur either by an activated jump (Ω_1) or by an entropic mechanism (Ω_2), and the total jump probability Ω is given by

$$\Omega = \Omega_1 + \Omega_2(1 - \Omega_1), \quad (19)$$

which suggests that the entropic process, Ω_2 , only applies to the unsuccessful first (activated) process, Ω_1 . Under these conditions, the cationic conductivity becomes

$$\sigma_i T = x \frac{e^2 \lambda^2 \nu}{6k_B} \exp \left(- \frac{\Delta G_f/2}{k_B T} \right) [\Omega_1 + \Omega_2(1 - \Omega_1)]. \quad (20)$$

At temperatures slightly higher than the glass transition, the two mechanisms participate in charge carrier mobility, leading to a deviation from an Arrhenius law. At higher temperatures, Ω_2 is expected to prevail over Ω_1 and Eq. (18) thus becomes

$$\sigma_i T = x \frac{e^2 \lambda^2 \nu}{6k_B} \exp \left(- \frac{\Delta G_f/2}{k_B T} \right) \exp \left(- \frac{B}{k_B(T - T_0)} \right), \quad (21)$$

which accounts for the nonlinear variations of the $\sigma_i T$ product in an Arrhenius plot (Figure 1).

5 Electronically Conductive Glasses

5.1 Band Scheme and Localized States in Covalent or Ionic Glasses

Amorphous silicon is a good example to summarize the main features of bonding relevant to electron conduction in oxide glasses. In this material, Si atoms are linked to four other atoms by four σ_{sp^3} covalent bonds of the valence band. The empty conduction band is formed from the empty antibonding $\sigma_{sp^3}^*$ orbitals. Owing to the distributions of bonds angles or bond lengths, the limits of the valence band and conduction band are less well defined than in a crystal, and some “band tails” of localized states slightly reduce the band gap energy. When disorder is more significant, bonds between two silicon atoms are broken and form free sp^3 atomic orbitals, also called dangling bonds D. Each dangling bond may contain zero, one, or two electrons, forming the D^+ , D^0 , and D^- electronic defects, respectively. A donor state would be a D^- dangling bond susceptible to lose an electron to a D^+ or D^0 acceptor site. As sketched in Figure 4, these dangling bonds are localized in the middle of the band gap, where they fix the Fermi level.

Electronically conductive oxide glasses bearing transition metals represent another example of an electronic transport through localized states in the band gap. According to a simplified ionic description of a silicate glass, the valence band would be an O^{2-} full p band,

Figure 4 Band scheme for amorphous silicon. (a) Origin of valence and conduction band states. (b) Associated density of states. Note the dangling bonds band fixing the Fermi level near midgap. Source: Sketched from Elliott [27].

and the conduction band an empty sp^3 band of Si^{4+} . When transition metal (M) oxides are incorporated in the glass structure, they are usually found in different oxidation states, M^{n+} and M^{n+1} , which introduce localized donor (M^{n+1}) and acceptor (M^{n+}) states in the band gap and pin the Fermi level.

5.2 Temperature Dependence of Electronic Conductivity

The techniques used to measure electronic conductivity do not need to be described as they are basically the same as for ionic conductivity. Because electron transfer at the electronically conductive glass/electrode interface is less energy dissipative, however, dc techniques simpler than impedance measurements can be used. When the temperature is increased from ambient conditions, one then finds that the variations of the electronic conductivity, σ_e , is described by equations similar to those presented for ionic conductive glasses, Eqs. (2) and (3):

$$\sigma_e = \frac{A_e}{T} \exp\left(-\frac{E_a}{k_B T}\right). \quad (22)$$

On the other hand, much below room temperature (Figure 5), the exponential dependence of conductivity tends progressively toward

$$\sigma_e \propto \exp\left(-\frac{B}{T^{1/4}}\right). \quad (23)$$

The exponent $1/4$ is the reciprocal of the effective dimensionality for the electronic transfer. An electron can jump only when two sites are close in the four coordinate space x, y, z, E .

5.3 Possible Electronic Transport Mechanisms

In oxide glasses, electronic displacements occur by electron transfer between two oxidation states of a given transition metal M. These two states, M^{n+} and M^{n+1} , result from redox reactions during glass synthesis involving oxygen from the atmosphere or other reservoir:

a reaction whose equilibrium constant depends on temperature, pressure, and chemical composition (Chapter 5.6). After quenching, the kinetics of the redox reaction are exceedingly sluggish so that the relative concentrations of the two valence states remain constant. Electronic conductivity then proceeds by successive electron transfer between the two oxidation states. Obviously, the probability that such a transfer occurs is greater when the two oxidation states are present in comparable concentrations. For this reason, vanadium oxide-based glasses have been studied more extensively, since, under usual synthesis conditions in air, the two valence states, V^{+IV} (d^1 configuration) and V^{+V} (d^0 configuration), have similar concentrations.

In its reduced state, the transition metal cation (M^{n+1}) has by definition a lower positive charge than in its oxidized state (M^{n+}). Consequently, the neighboring negatively charged oxygen anions are less attracted and at a greater distance than in the oxidized form. This local distortion and the electron that create it are called a “polaron,” a quasiparticle to which is thus associated a wave function. When this local distortion does not extend over the first neighboring atoms, the polaron is designated as “small,” which is the usual case for oxide

Figure 5 Electronic conductivity of three V_2O_5 - TeO_2 - Bi_2O_3 glasses as a function of temperature for the mole fractions indicated [28]. (a) Conductivity increases with increasing V_2O_5 molar ratio, fits being made to the data with Arrhenius equation (22). (b) Linear plots of the same dc data against $T^{-1/4}$, consistent with the variable range hopping Eq. (23).

glasses. The small polaron may be transferred from the reduced to the oxidized form of the transition metal cation by different mechanisms at high and low temperatures.

At high temperatures – typically $T > \Theta/2$ where Θ is the Debye temperature ($\Theta = 500$ K for SiO_2 glass) – lattice vibrations cause the surroundings of the donor and acceptor sites to have, temporarily, the same energies so that only electrons are transferred by tunneling from the reduced to a neighboring oxidized valences (Figure 6). In an intermediate state (Figure 6b), the electron is delocalized between the two metal cations. This electron delocalization can be also seen as the formation of a molecular orbital (Figure 7) between the d orbitals of two vanadium ions, for instance, and the p orbital of a bridging oxygen. A binding energy J is associated with the formation of this transition state, and the total energy required for the electron transfer can be written as $E_a = 1/2W_p - J$, where $1/2W_p$ is the energy provided by the lattice

to equalize the energy levels of both donor and acceptor sites.

With this approach, Mott and Davis [29] derived the following expression for electronic conductivity:

$$\sigma_e T = x \frac{e^2 \lambda^2 \nu_p}{k_B} y(1-y) \exp(-2\alpha\lambda) \exp\left(-\frac{E_a}{k_B T}\right), \quad (25)$$

where x is the total concentration of the transition metal, ν_p the phonon frequency giving rise to the equalization of the energy levels of the donor and acceptor sites, λ the distance between two neighboring sites, y the molar ratio of the reduced form, and α the exponential electronic decay of the d orbitals. This expression can be seen as the product of three probabilities: (i) the $y(1-y)$ term, which is the probability of finding an acceptor site close to a donor site; (ii) $\exp(-2\alpha\lambda)$, that of an electronic transfer occurring between two adjacent sites; and (iii) $\exp(-E_a/k_B T)$, that of locally providing the energy necessary to form the transition state. All the temperature-independent terms can be gathered in a single A_e term, namely,

$$A_e = x \frac{e^2 \lambda^2 \nu_p}{k_B} y(1-y) \exp(-2\alpha\lambda). \quad (26)$$

Within a limited range of temperatures, this expression accounts for the experimental results represented by Eq. (22) where activation energies (E_a) range from 0.3 to 0.5 eV and the pre-exponential term (A_e) from 10 to 10^2 K S cm $^{-1}$, being lower than in ionic conductive glasses.

At low temperature, typically for $T < \Theta/2$, the electron and the associated local deformation may move simultaneously by tunneling from the donor (M^{n+1}) to an acceptor (M^{n+}) site. Physically, this means that the mean thermal energy $k_B T$ is too low for the activation energy

Figure 6 Sketch of electron hopping by a phonon-assisted tunneling process. (a) Before hopping. (b) Phonon-activated transition state. (c) After hopping.

Figure 7 Electronic delocalization during electron transfer between two vanadium cations, implying the formation of π bonds between the d orbitals of vanadium cations and a p orbital of a bridging oxygen.

E_a to be overcome locally so that tunneling transfer may occur over several interatomic distances, i.e. at a distance $R \gg \lambda$, until an acceptor site with a similar energy is found for the donor site. Mott called this process “variable range hopping” [29] and estimated R as a function of temperature and $N(E_F)$, the density of states near the Fermi level, to be

$$R \approx [\alpha k_B T N(E_F)]^{-\frac{1}{4}}. \quad (27)$$

At low temperatures, this expression thus describes the temperature dependence of conductivity as expressed by Eq. (21).

5.4 Electronic Switching Effect in Oxide and Chalcogenide Glasses

Although attention has been paid in this chapter to oxide glasses, the basic concepts presented apply to other classes of glasses as well. Covalent and chalcogenide glasses are cases in point with their electronic conductivity occurring by means of electron transfer between localized states in the band gap, which is phonon assisted over $\Theta/2$, and by a variable range hopping below this value. Of particular interest is the “switching effect,” originally described by Ovshinsky [30] in 1968 on a Te–As–Si–Ge glass, which consists of a sudden increase in the electronic conductivity of the glass, by up to six to eight orders of magnitude, in response to the application of a sufficiently high electric field. Such a switch was later observed in a large variety of chalcogenide and also in oxide-based glasses. Between the conductive (“on”) and resistive (“off”) states, the effect is very fast as it takes less than 10^{-9} s and it is also reversible, currently over 10^{10} cycles. It is thus actively studied, mainly for the storage of binary information. Two main mechanisms have been identified.

The first, the threshold switch, is considered to be a pure electronic mechanism [31]. The localized states in a glass pin the Fermi level near the center of the gap and provide the high resistance of the “off” states described in Section 2.2. Under an electric field of about 10^5 V cm $^{-1}$, the injected electrons and holes from the electrodes fill the empty localized levels and generate a conductive plasma made of a degenerate electron and hole gas. A high electronic conductivity (“on” state) appears, called the threshold switch. This conductive state returns to the resistive state below a minimum value of the applied voltage, the *holding* voltage.

The second mechanism is called memory switch [7]. In this case, local Joule heating brings about controlled and reversible precipitation of a crystalline phase of much higher electronic conductivity than that of the glass. The “off” to “on” transition results from heating the glass

to just above T_g , where fast crystallization produces conducting paths in the form of filaments forming throughout the thickness of the film. The current pulse then causes the reverse transition to take place through melting of the filaments. By heat loss to the surrounding material, the molten filaments are quickly quenched to the original glass phase, returning the film to the low conductive “off” state. In this case, the “on” state does not need a holding voltage to store the information. Commercial memories based on these properties are called phase change memories (PCM). They are currently able to store up to 512 Mbits on a simple chip. In this case, glass compositions are chosen to allow for devitrification with low structural cross-linking as $\text{Ag}_5\text{In}_5\text{Sb}_{60}\text{Te}_{30}$ or $\text{Ge}_2\text{Sb}_2\text{Te}_5$ alloys [31].

6 Perspectives

The main characteristics of ionic transport are its high sensitivities to both temperature and glass composition. As described here, one can deal with them comprehensively by associating classical theories for ionic transport in ionic crystals and molten salts (sensitivity to temperature) and weak electrolyte solutions (sensitivity to composition). Despite several thousand papers published on the subject, however, the mixed alkali effect (Chapter 4.6) remains a permanent challenge and a test of the validity of all thermodynamic or microscopic approaches.

In the last 20 years, fast ionic conductive glasses have been synthesized, especially with Li^+ or Ag^+ cations. Their room-temperature conductivity reaches values close to that of usual electrolyte solutions, i.e. 10^{-3} – 10^{-4} S cm $^{-1}$, offering a promising potential for new applications as active components in thin film solid-state batteries (Chapter 9.5), electronic memories, or stamping processes.

Interest in electronic conductive glasses has been boosted by successful applications of their switching properties in electronic devices or their photoconductive properties. A particularity of most electronic-conductive oxide glasses is that they may simultaneously present ionic and electronic conductivities. Thus, they may include foreign atoms electrochemically into their vitreous structure by simultaneous electronic and ionic injections. This possibility will in particular lead to further advances in electrochromic devices (smart windows), glass electrodes associated with a glassy electrolyte in solid-state batteries, and programmable metallization cell memories.

In its p and n types, amorphous silicon probably exemplifies best the practical importance of electronic

conduction. To form these semiconductors, the first step is to eliminate the dangling bonds and their associated localized states in the band gap by glow discharge decomposition of silane, SiH_4 , on amorphous silicon through the formation of $\text{Si}-\text{H}$ bonds whose bonding states lie deep within the valence band. Mixing some fraction of gaseous PH_3 or B_2H_6 with the silane then produces either n- or p-type conductive amorphous silicon. The donor (P) or acceptor (B) states are located close to the conduction or valence bands, allowing for electronic conduction in these bands (extended states). These amorphous semiconductors are now used in the design of solar cells whose lower cost compensates for lower yields.

4.3

Diffusion in Oxide Glass-forming Systems

Huaiwei Ni¹ and Nico de Koker²

¹ CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei, China

² Department of Civil Engineering, Stellenbosch University, Stellenbosch, South Africa

1 Introduction

When oxide glasses are synthesized from a heterogeneous mixture of starting products, homogenization of the chemical composition during the melting process is ultimately achieved through diffusion (Chapter 1.3). Likewise, the chemical and physical durability of glasses is often controlled by diffusion kinetics [1]. Diffusivity, the property characterizing the timescale of diffusion, is in addition an indispensable parameter for understanding magmatic processes, such as magma mixing and the growth of crystals and bubbles from silicate melts. Beyond practical applications, the variations of diffusivity with either the nature of atomic species or with changing physicochemical parameters provide important insight into the structure of oxide glasses and melts. Diffusion is also intimately associated with other transport processes, such as viscous flow and electrical conduction.

These various features will form the backdrop of this chapter where we will first describe diffusion in physical and chemical terms and continue with a summary of the experimental methods used to measure diffusivities. The influence of species properties, composition (X), temperature (T), and pressure (P) on diffusivity will then be systematically examined. We end with a discussion of the investigation of diffusion with atomistic simulations and a consideration of possible future developments.

2 Physical and Chemical Description of Diffusion

2.1 Fick's Laws

Diffusion, an important means of mass transport, reflects thermally activated random walks of atomic species. The rate of diffusion is described by *diffusivity* or *diffusion coefficient* (denoted as D) with an SI unit of m^2/s . Because oxide gases and melts are isotropic systems, diffusivity is a scalar and is uniform in all directions. From a phenomenological perspective, a concentration gradient of a given component (∇C) will result in a net flux of that component as

$$\mathbf{J} = -D\nabla C, \quad (1)$$

known as Fick's first law of diffusion. Rigorously speaking, $\mathbf{J}$ arises from a chemical potential gradient ($\nabla\mu$), which is termed the thermodynamic driving force for diffusion. Diffusion acts to erase any heterogeneity across the system and leads to entropy production, as was elegantly treated by Onsager [2] in the framework of nonequilibrium thermodynamics. Readers are referred to [3] for a concise summary of the thermodynamic basis of the diffusion process. For diffusion in a non-steady-state system constrained by mass conservation, the concentration at a point space changes with time (t) as the divergence of $\mathbf{J}$,

$$\partial C / \partial t = \nabla \cdot (D\nabla C), \quad (2)$$

which is known as Fick's second law of diffusion. Analytical solutions of Eq. (2) for various initial and boundary conditions are available in [4].

2.2 Diffusion Mechanisms

From an atomistic perspective, diffusion can occur through a variety of mechanisms. At temperatures below the glass transition, a glass is essentially a solid with an

Reviewers: H. Behrens, Institut für Mineralogie, Leibniz Universität Hannover, Hannover, Germany
C. Leshner, Geology, University of California at Davis, Davis, CA, USA

amorphous network structure hereafter referred to as the *matrix*. Hence, the diffusion mechanisms operating in glasses are similar to those found in crystalline solids, albeit with a larger variety of structural sites.

A small neutral atom such as He can jump from one interstitial site to another through a bottleneck or energetic saddle point, interacting negligibly with the matrix. This process is referred to as the *direct interstitial mechanism*. When the atom (or ion) in question is of similar size as matrix atoms, two neighboring atoms may exchange their positions. However, this *direct exchange* mechanism is energetically very unfavorable. A rotational move of three or more atoms in concert entails less matrix distortions, but such a *ring mechanism* is rather complex. Another collective mechanism of diffusion is the *indirect interstitial* mechanism (or *interstitialcy mechanism*), with which an interstitial atom replaces a matrix atom, and the latter enters into an interstitial site. Still, the easiest pathway for diffusion is atom hopping into a vacant matrix site, referred to as the *vacancy mechanism* (see [1, 5] and Chapter 4.2 for more details about the mechanisms of ionic transport in oxide glasses).

In contrast to glasses, either stable or supercooled melts are intrinsically dynamic systems characterized by continuous occurrence of ionic transport, bond breaking and formation, and the interconversion of differently coordinated species. These interatomic rearrangements are collectively termed structural relaxation (Chapter 3.7). For small neutral species, the diffusion mechanism in a melt may not be fundamentally different from that in a glass (i.e. the interstitial mechanism). But for ions more closely contributing to structural relaxation (e.g. network-forming cations), diffusion may involve the formation of complex transition-state species, such as five-coordinated Si in the case of silicate melts. Upon cooling, relaxation time increases, and a melt is transformed into a glass at the glass transition temperature (T_g), where the relaxation time becomes longer than the timescale of the experiment (Chapter 3.7). That is, structural relaxation essentially stops.

2.3 Diffusion Distance

By considering the collective motion of Brownian particles, Einstein [6] derived that the diffusivity of an atomic species is related to its mean-square displacement $|\mathbf{R}(t) - \mathbf{R}(0)|^2$ by

$$D = \lim_{t \rightarrow \infty} \frac{\langle |\mathbf{R}(t) - \mathbf{R}(0)|^2 \rangle}{6t}. \quad (3a)$$

Alternatively, diffusivity may be described as

$$D = \frac{L^2 \nu}{6} f, \quad (3b)$$

where L is the jump distance, ν is the jump frequency, and $f (\leq 1)$ is the correlation factor that is introduced because the jump probability may depend in part on the preceding jump. As an example, f approaches unity in the case of a tiny amount of a diffusing species hopping by the interstitial mechanism. From Eq. (3a), the diffusion distance in a given direction (x) can be estimated with

$$\Delta x \approx \sqrt{2Dt}. \quad (4)$$

Both Eqs. (3a) and (4) are referred to as the Einstein–Smoluchowski equation. Of particular practical interest is the fact that any process obeying Eq. (4) may be assumed to be diffusion controlled. This is, for example, the case of the kinetics of redox reactions (Chapter 5.6).

2.4 Types of Diffusion

In describing a diffusion process, the reference frame used is of key importance. This is why theoretical simulations invariably involve a fixed origin with respect to which all coordinates are described. Likewise, a reference point or plane on the material is also required in experimental studies. As driven by gradients in chemical potential, diffusion in a multicomponent glass-forming system must in addition be referred to some elements of the matrix: diffusion of a specific component is called *self-* or *cross-diffusion* depending on whether it is referred to itself or to other components. In atomistic simulations, individual atoms can be distinguished, so self-diffusivity is straightforward to derive with Eq. (3a).

Experimentally, however, individual atoms cannot be tracked so that the trick used to investigate self-diffusion is to introduce a distinct isotope, often radioactive, of the same element (whose mass difference may introduce some bias). In practice, the most common case of self-diffusion is that of *tracer diffusion* when ppm amounts or less of an isotopic tracer are introduced so as to produce only negligible concentration gradients [3, 7].

Diffusion in a system of three or more distinct chemical species is referred to as *multicomponent diffusion*, the special case of two species being known as *binary diffusion*. Owing to cross-diffusion in multicomponent systems, *uphill diffusion* (aligned $\mathbf{J}$ and ∇C) may occur, representing an apparently negative diffusivity that gives rise to an increase of the gradient of chemical composition (but not in chemical potentials). Finally, diffusion may be complicated by a chemical reaction, such as the interconversion between H_2O and OH in the case of H diffusion. This situation is referred to as *multispecies diffusion* [7]. These complexities notwithstanding, our

discussion will focus mostly on the self-diffusivity or tracer diffusivity of individual components or species.

3 Experimental Methods for Determining Diffusivity

The diffusivity of atomic species at fixed temperature (T) and pressure (P) in oxide glasses and melts can be determined by direct or indirect methods. The former are based on Fick's law of diffusion. Appropriate analytical techniques are applied to measure a diffusion profile or a bulk exchange produced by a thin source, a diffusion couple, or other methods [4, 5, 8]. For volatile components, membrane permeation, sorption, and desorption methods are frequently used [9].

Indirect methods investigate other physical phenomena related to diffusion. If electrical conduction in an oxide glass or melt is dominated by the transport of a single ion (such as Na^+), the diffusivity of that ion may be derived from the measured electrical conductivity (σ) via the Nernst–Einstein equation:

$$D = H_R \frac{k_B T \sigma}{N q^2} = H_R D_\sigma, \quad (5)$$

where k_B is the Boltzmann constant, N and q are the number density (in m^{-3}) and charge (in C) of the ion, respectively, and H_R is the Haven ratio determined by the diffusion mechanism and the correlation factor (Chapter 4.2). The *conductivity diffusion coefficient* D_σ is usually greater than the self-diffusivity D (hence $H_R \leq 1$). Another electrical method is square-wave voltammetry, which can be used to quantify the diffusivity of heterovalent elements in low-viscosity melts (Chapter 5.9).

Several compilations of diffusivity data in oxide glasses and melts are available [9–12]. For convenience, selected data sets are presented in Tables 1 and 2 for silicate and nonsilicate systems, respectively. The following three sections will elaborate on the variation of diffusivity with the intrinsic properties of diffusing species and the basic extrinsic parameters composition, temperature, and pressure. For a glass, thermal history (which governs T_g) may also have a detectable effect on diffusivity. Indeed, the dependence of properties on thermal history is an obvious indicator that a glass is not in internal thermodynamic equilibrium (Chapter 3.2).

4 Influence on Diffusivity of Species Properties

As illustrated in Figure 1 by comparisons between silica and albite ($\text{NaAlSi}_3\text{O}_8$) glasses and melts, atomic species show distinct diffusivities under similar T , P conditions.

The role played by the mass of the diffusing species is insignificant. By contrast, valence and size are two determining factors of diffusivity. Because of weaker interactions with the matrix, species with a small size and low electrical charge requires less energy to diffuse. Not surprisingly, neutral molecules and alkalis thus have higher diffusivities than other groups of elements (Figure 1). For species with valence $Z = 0$ or ± 1 , diffusivity always decreases with species size within each group (e.g. noble gases, alkalis, and halogens). However, this trend no longer holds for ionic species with $|Z| > 1$ (such as alkaline earths in Figure 1b); instead, diffusivity may increase with ionic radius (r). This effect probably results from decreasing field strength (Z^2/r), as r increases, which induces a weaker impeding response from the surrounding charge density.

Broadly speaking, volatile species diffuse faster than network-modifying cations, which in turn diffuse more rapidly than network-forming cations (such as Si^{4+} in silicate systems). The diffusivity of volatile species and low-field-strength network modifiers (such as Na^+) depends more favorably on their intrinsic properties and may therefore be referred to as *intrinsic diffusivity* [13]. That is, these species move largely on their own. By contrast, the diffusivity of network formers be referred to as *extrinsic diffusivity* because it is intimately associated with the matrix structure and is therefore more sensitive to extrinsic parameters (X , P , T), which primarily affect the network structure. Below the glass transition, network formers are essentially immobile. At high temperature, the extrinsic diffusivity may approach the *viscosity diffusion coefficient* D_η calculated with the Stokes–Einstein relation,

$$D_\eta = (k_B T) / (6\eta\pi r), \quad (6a)$$

where η is viscosity, from the assumption that diffusion and viscosity involve the same structural entities. For silicate and possibly other oxide glass-forming systems, however, the Eyring relation based on the transition-state theory [14] is more appropriate,

$$D_{\text{Eyr}} = (k_B T) / (\eta L), \quad (6b)$$

where D_{Eyr} is the *Eyring diffusivity* and L is the jump distance often taken as 2.8 Å, the diameter of the O^{2-} ion. A close match often exists between D_{Eyr} and the extrinsic diffusivity as represented by Si and O diffusivities in silicate melts, except when O diffuses by a shortcut mechanism, such as transport by H_2O or O_2 (Figure 1).

The diffusivity differences between various species shrink with increasing temperature and pressure and depend to some extent on composition. At least for silicates at $T < 2000$ K and $P < 2$ GPa (Table 1; Figure 1),

Figure 1 Contrasts between the effects of size and electrical charge on atomic diffusivities in glasses and melts of silica (a) and albite (b) [9, 12]. Atomic or ionic radii for a coordination number of 4 for Si, Ga, and F; 6 for noble gases, divalent cations, and O; and 8 for alkalis. Eyring diffusivities included as a horizontal line for comparison. The faster diffusion of O than Si in silica melt may be due to a shortcut mechanism.

however, chemical species can be roughly lined up in a diffusivity sequence:

$$\begin{aligned} \text{Si} < \text{REE} < \text{Mg} < \text{Xe} < \text{Cs} < \text{Ba} \approx \text{Kr} \approx \text{Sr} \approx \\ \text{Ca} < \text{Rb} \approx \text{Ar} \approx \text{CO}_2 < \text{K} < \text{Ne} \approx \text{Na} \approx \text{Li} < \text{He}, \end{aligned} \quad (7)$$

where REE indicates the rare earth elements.

5 Compositional Control

Chemical composition determines the structure of a glass-forming system and sets up the matrix environment for diffusion. But the compositional control on diffusivity

is complicated and difficult to model, to say the least. As implied by Eqs. (6a and 6b), diffusivity, for example, generally decreases with increasing viscosity which, other things being equal, generally means an increasing degree of polymerization or increasing concentration of network formers. Rather robust as is this rule, there are still a number of exceptions to it.

5.1 Silicate Systems

Silicates are the most comprehensively studied among all kinds of oxide glass-forming systems. In this case, the concentration of SiO_2 may be conveniently used as a first-order index of polymerization. Assuming Si, Al, and ferric iron to be network formers, one measures more accurately (de)polymerization as the number of non-bridging oxygen atoms per tetrahedrally coordinated cation as $\text{NBO}/T = [2 \text{ O}/(\text{Si} + \text{Al} + \text{Fe}^{3+}) - 4]$ [15]. From basalt to andesite to dacite to rhyolite compositions (Figure 2), the diffusivity of Si among most other ions decreases rapidly along the sequence of decreasing NBO/T for natural calc-alkaline melts, in agreement with the trend predicted by Eqs. (6a and 6b). However, there appears to be a slight concomitant increase in Na diffusivity (Figure 2). One possible explanation for this special phenomenon is that rhyolitic melt has a higher “ionic porosity” or “free volume,” the fraction of melt volume not occupied by ions, than basaltic melt [13].

Volatiles, and water in particular, have a tremendous effect on diffusivity in silicate systems. Adding H_2O promotes the diffusion of all species as it disrupts the network structure through the reaction $\text{H}_2\text{O} + \text{SiOSi} = 2 \text{ SiOH}$, with an associated drop in viscosity. The enhancing

Figure 2 Na and Si diffusivities in natural silicate melts with different degrees of polymerization [12]. Water has a more pronounced influence on Si diffusivity than on Na diffusivity.

role of water on diffusivity is especially strong for ions with high field strength, such as Si^{4+} (Figure 2).

5.2 Nonsilicate Systems

Diffusivity data for nonsilicate systems are limited. In borate glasses $x \text{ Na}_2\text{O} \cdot (100 - x) \text{ B}_2\text{O}_3$, He diffusivity decreases with x increasing from 0 to 7.3, whereas Na diffusivity increases with x increasing from 12 to 24 (Figure 3a). As Na_2O is added to vitreous B_2O_3 , progressively more trigonal boron converts to tetrahedral configuration, which entails the *boron anomaly* and ensures the chemical stabilization of borate glass (Chapter 7.6). Only after x reaches ~ 25 , does borate glass start being depolymerized by further Na_2O incorporation [5]. The combined He and Na diffusivity data appear to be

Figure 3 Differing effects of network-former coordination changes on He and Na diffusivities in alkali borate (a) and alkali germanate (b) glasses [10].

qualitatively consistent with this structural analysis, except that the diffusivity minimum, at least for Na, is expected to be at $x < 10$ instead of at $x = 25$.

Diffusivity minima have been unambiguously observed in germanate glasses $x \text{ Na}_2\text{O} \cdot (100 - x) \text{ GeO}_2$, at $x \approx 19$ for He and $x \approx 9$ for Na (Figure 3b). As found for borate glasses, the observed trend for germanate glasses is associated with a coordination change of the network former, in this case the transformation of tetrahedral Ge to octahedral Ge, until the appearance of non-bridging oxygen at $x \approx 18$. Loose bonding between Na^+ and $[\text{GeO}_{6/2}]^{2-}$ or $[\text{BO}_{4/2}]^-$ group may account for the early increase of Na diffusivity [1].

By comparing Na diffusivity in various types of binary glasses with similar mole fraction of Na_2O (~ 0.16 , except for the phosphate), one finds that Na diffusion becomes slower from phosphate to silicate to germanate and to borate glass (Figure 4). While this trend may not be absolutely transferrable to the diffusivity of other species, it does appear to be consistent with the fact that the proportion of non-bridging oxygen decreases along this sequence.

5.3 Mixed Alkali Effect

A special phenomenon manifesting the complexity of compositional control is the so-called mixed alkali effect. Take a series of 20 $[x \text{ Na}_2\text{O} \cdot (1 - x) \text{ Rb}_2\text{O}] \cdot 80 \text{ B}_2\text{O}_3$ glasses as an example (Figure 5): as x increases from 0 to 1 (i.e. Rb is progressively replaced by Na), the Rb diffusivity monotonically decreases; likewise, a slowdown of Na diffusion occurs with decreasing x . At the end-member composition 20 $\text{Rb}_2\text{O} \cdot 80 \text{ B}_2\text{O}_3$, the Na diffusivity even drops below

Figure 4 Influence of the glass matrix on Na diffusivity in various types of binary glasses with similar mole fraction of Na_2O (except for the phosphate) [10].

Figure 5 The mixed alkali effect as indicated by the variation of Na and Rb diffusivities and electrical conductivity in alkali borate glasses [5].

that of Rb, overturning the normal sequence of Eq. (7). Therefore, each alkali seems to impede the diffusion of the other alkali, resulting in a marked minimum in the electrical conductivity of glass (Figure 5). The mixed alkali effect is more pronounced with increasing size mismatch of the two alkalis and is common in all types of oxide glasses. However, there is still no consensus on its physical origin, with the electrodynamic interaction models, the hydrostatic stress models, and the defect models as the favored candidate mechanisms [1, 5, 16].

6 Temperature and Pressure Effects

6.1 Temperature Effects

For a given composition and a given species, diffusivity always increases with temperature and usually decreases with pressure, although there are fascinating exceptions in glass-forming systems that have provided significant insight into the mechanisms of diffusion. The “normal” behavior is often well described by an Arrhenius relation, which follows from the mechanical description of diffusion in the framework of Boltzmann statistics [3],

$$D = D_0 \exp\left(-\frac{H_a}{RT}\right) = D_0 \exp\left(-\frac{E_a + P\Delta V_a}{RT}\right), \quad (8)$$

where D_0 is the pre-exponential factor, H_a and E_a are the activation enthalpy and activation energy, respectively, ΔV_a is the activation volume, and R is the gas constant. The Arrhenius parameters D_0 and H_a are summarized in Tables 1 and 2 for silicate and nonsilicate systems.

Figure 6 Convergence of diffusivities in a rhyolitic melt in the high-temperature limit [12].

For some volatiles, one describes diffusivities better by taking D_0 to be proportional to temperature [9].

In view of the thermally activated nature of the diffusion process, H_a and E_a are positive so that, as already noted, diffusivity always increases with temperature. For the diffusion of various species in a matrix of given composition, the sequences of E_a and diffusivities are generally opposite. The activation enthalpy can be as low as ~ 20 kJ/mol for He diffusion and as high as ~ 400 kJ/mol for Si diffusion (Tables 1 and 2). This negative correlation between E_a and D_0 is known as the compensation law and has the important consequence that diffusivities tend to converge in the high-temperature limit (Figure 6). With decreasing temperature, the diffusivities of atomic species decrease following divergent paths governed by E_a , which expresses the decoupling between atomic mobility and structural relaxation [15].

Below the glass transition range or above the liquidus, the linear relationship between the logarithm of diffusivity and $1/T$ implied by Eq. (8) is rather robust. Some experimental data even suggest a constant H_a across the glass transition. However, there is also evidence for a change of H_a between glass and melt, which has important implications for the common first-order view of glasses as effectively frozen-in liquid structures. For O and Na diffusion in a soda-lime silicate (i.e. a window glass), two linear segments of $\ln D$ versus $1/T$, with different slopes, are connected by a nonlinear curve in the intermediate temperature range (Figure 7). Intersection of the curve and the low-temperature segment produces an inflection point close to T_g , which is more easily recognizable for O than for Na. In other systems, the inflection point in the Na diffusivity curve can be lower than the calorimetric T_g by up to 100 K. The oxygen diffusivity

Figure 7 Effects of the glass transition (T_g) on the diffusivities of O and Na in a soda-lime silicate system, with the Eyring diffusivity shown for comparison [15].

approximates the Eyring diffusivity at high temperature, but their difference increases substantially down to T_g .

Cooling results in an increase in the relaxation time of the α -process (or the primary relaxation) which, as controlling viscous flow, is the major component of structural relaxation [17]. When plotted against $1/T$, the reciprocal of relaxation time has a shape similar to the Eyring diffusivity curve in Figure 7. In oxide glasses below T_g , the Arrhenius nature of diffusivity indicates that diffusion belongs to the category of β -processes (or secondary relaxations), which are associated with shorter timescales and less structural modification than the α -process [17]. In oxide melts, the combination of the α - and β -processes may explain the complex temperature dependence of diffusivity in the intermediate temperature range above T_g (Figure 7). With increasing temperature, the α -process will eventually take over control of diffusion, sooner for network formers and oxygen than for network modifiers.

6.2 Pressure Effects

In glass science, the pressure dependence is not of major concern to diffusion. Limited studies [18] have yielded activation volumes of $6\text{--}33 \times 10^{-6} \text{ m}^3/\text{mol}$ at $P < 1 \text{ GPa}$ for Na and Rb diffusion in alkali borate glasses (Figure 8a).

In earth and planetary sciences, diffusion in silicate melts under high pressure has in contrast been investigated extensively for application to geological processes at great depths. The effects of pressure on the diffusion of most species (such as for Ar, Figure 8b) are negative, which can be understood in light of the “free volume” concept. In polymerized melts, however, Si and

Figure 8 Pressure effect on diffusivity in alkali borate glasses (a) and natural silicate melts (b) [9, 18].

O diffusivities first increase with pressure (corresponding to negative ΔV_a), before the trend reverses at several GPa (Figure 8b). Consistent with Eq. (6b), the positive pressure influence on Si and O diffusivities is often accompanied by a decrease of melt viscosity. These effects are associated with pressure-induced changes in melt structure, which however act little on the diffusion of network modifiers and volatiles.

7 Insights from Molecular Dynamics Simulations

Thanks to the advances in computation technology, molecular dynamics (MD) simulations can now be readily used to investigate diffusion in oxide melts at high T and P that are difficult to achieve experimentally. In addition to their practical interest, they provide an intrinsically

atomistic perspective. The computationally expensive first-principles molecular dynamics (FPMD) is afflicted by limits on simulation size and time, but theoretically delivers more accurate results than classical MD. A detailed treatment of computational studies of diffusion is given in [3] and Chapter 2.9.

Although discrepancies between experimental and computational diffusivities occur, computations show their true power in elucidating the underlying structural rationale and relative trends of D versus X , P , T . For example, the increase of Si and O diffusivities with pressure in polymerized silicate melts was predicted by MD simulations [19] before it was experimentally confirmed. MD simulations further indicate that this phenomenon is associated with pressure-induced changes in the lifetimes of Si coordination species.

Owing to the short timescales involved, MD is only viable for high-temperature investigations, i.e. for liquid systems. Other techniques for characterizing diffusion in solids are available, but are usually only applied to crystalline materials. In addition, the currently accessible system sizes of MD simulations pose limits to inquiry as the glass transition is approached, as locally heterogeneous dynamics with slow and fast diffusing regions may lead to non-ergodic behavior, and long-range interactions are likely to play an important role.

8 Perspectives

An enormous amount of diffusivity data in oxide glass-forming systems has been collected in the past century with a variety of experimental methods. From a phenomenological point of view, we have attained substantial appreciation on how diffusivity varies with species properties, composition, temperature, and pressure. However, the physical rationale behind the observed trends is not totally clear yet. The mixed alkali effect and the temperature dependence of diffusivity in the vicinity of glass transition are just two examples of complex diffusion phenomena that need further investigation.

A complete account of the interactions between atoms may hold the key to understanding the mechanisms of diffusion and the trends of diffusivity. In essence, diffusion and structural relaxation in glass-forming systems are many-body problems, which unfortunately remain unresolved in condensed matter physics and statistical mechanics [20]. In that regard, first-principles simulations, which make no a priori assumption of interatomic interactions, have the potential to bring major breakthroughs. On the basis of a deeper understanding of the physics of diffusion, along with the accumulation of

more reliable experimental and computational diffusivity data, it will then become possible to develop much needed multivariate diffusivity models, which will find plenty of applications in the development of new oxide glasses.

Chemical Diffusion in Multicomponent Glass-forming Systems

Mathieu Roskosz¹ and Emmanuelle Gouillart²

² Surface du Verre et Interfaces, Joint Unit CNRS/Saint-Gobain, Aubervilliers, France

1 Introduction

Diffusive processes are of pivotal importance in the glass-making industry. Whereas advection, for instance, plays a major role in large-scale mixing of the molten batch, small-scale chemical heterogeneities are erased by diffusive transport (Chapters 1.1 and 1.2). In the opposite direction, diffusion-controlled processes also take place to create chemical heterogeneities when devitrification or, more generally, any phase separation is induced as done in the production of glass ceramics (Chapter 7.11). Finally, glass durability is at least partially controlled by the diffusivities of chemical species such as water within the glass network. Whether upon fabrication or use, chemical diffusion is thus a fundamental process particularly relevant to glass. It remains to be understood better, however, especially to optimize glass manufacturing in terms of the temperature and composition dependences of the characteristic time and length scales of diffusion processes.

As a matter of fact, different quantities and concepts are intermingled in the general term of *diffusion*. First, the diffusion of a given component is more precisely named *self diffusion* when an atomic random walk is studied in reference to the component itself (Chapter 4.3). Experimentally, the self-diffusivity can be determined by isotopic tracing or from diffusion profiles of the component of interest present in trace amounts such that concentration gradients are negligible. This situation reproduces the common picture of diffusion of the random walk of a tracer in a solvent. From atomistic simulations, the self-diffusion coefficient can also be calculated and then related to transport properties such as viscosity

and electrical conductivity (cf. Chapter 4.6). A third kind of diffusion coefficients is associated with much more common industrial and natural systems where chemical heterogeneities are characterized by large concentration differences for one or several components. This general situation of mass transport leading to a local change in composition is referred to as *chemical diffusion* or *interdiffusion*. It is the subject of this chapter.

Because the composition gradients of different components may interfere with one another, the interdiffusion rate of a given component may widely differ from the rate deduced from its self- or tracer-diffusion coefficient in similar melts. From macroscopic, phenomenological, or mathematical approaches, diffusive processes can be studied in a variety of ways. As generally based on Fick's equations, however, these provide little insight onto the microscopic processes at work in glasses and melts. In their simplest form, macroscopic descriptions can in addition yield apparently paradoxical quantities such as *negative* diffusion coefficients in multicomponent systems (i.e. diffusion acting against the chemical gradients of components).

Mechanistic approaches are, therefore, needed to arrive at a comprehensive picture merging the kinetic and thermochemical aspects of chemical diffusion. This chapter will thus begin with a review of this theoretical background. After a brief description of the experimental procedures to be followed in interdiffusion studies, diffusion in binary melts and relationships between self- and chemical diffusion will be presented. The general case of multicomponent systems will then be dealt with, particular attention being paid to uphill diffusion and diffusion paths. Finally, the composition and temperature dependences of diffusive coupling will be examined from the results obtained on ternary and quaternary aluminosilicate systems.

2 Conceptual and Experimental Approaches

2.1 Fundamental Concepts

In 1855, the physician A. Fick (1829–1901) described diffusive mass transport by analogy with the celebrated heat equation published in 1822 by the mathematician J. Fourier (1768–1830). In isotropic media such as melts and glasses, Fick's first law thus relates the concentration gradient to diffusive flux of a component through

$$J = -D\nabla C, \quad (1)$$

where J , the diffusive density (analog of the heat flux), is negatively proportional to ∇C ; the local concentration gradient ($\sim$ temperature gradient), with a proportionality coefficient D defined as the *diffusion coefficient* ($\sim$ thermal conductivity), is expressed in the SI m^2/s unit. In the typical case where D is a positive scalar, a local change of the concentration of the element gives rise to a flux from the concentrated to the depleted part of the system. Equilibrium is then attained when concentrations ($\sim$ temperatures) are equal across the whole system.

If there are no sources or sinks for the component of interest and if convection is negligible, the concentration change of the component of interest in an elementary volume of the system is the difference between its incoming and outgoing fluxes. This mass conservation rule is referred to as Fick's second law and can be written for non-steady-state system as

$$\frac{\partial C}{\partial t} = \nabla \cdot (D\nabla C). \quad (2)$$

Analytical solutions of Eq. (2) have been given by Crank for a great many initial and boundary conditions [1]. Applications to multicomponent systems such as liquids and glasses of industrial and geological interest is not straightforward, however (cf. Chapter 4.3), because concentrations must sum to 1 (or 100%) at each point. In other words, any local decrease of the concentration of a component is compensated by increases of the concentrations of other components. In such systems, at least two gradients – and, therefore, two *fluxes* in opposite directions – are necessary to characterize the overall diffusive mass transport. How, then, can these fluxes be mutually related? The simple answer brought forward by Onsager [2] was to generalize Fick's equations with the assumption that the flux of component i is linearly related not only to its own concentration gradient but also to those of all other components:

$$J_i = -\sum_j (D_{ij} \cdot C_j), \quad (3)$$

where D_{ij} are the diffusion coefficients of component i along the concentration gradients of the other

components j . If one again assumes negligible convective transfer and the absence of sources or sinks for the component i , Fick's second law is expressed as

$$\frac{\partial}{\partial t} \begin{bmatrix} C_1 \\ \vdots \\ C_j \\ \vdots \\ C_n \end{bmatrix} = \begin{bmatrix} D_{11} & \cdots & D_{1j} \\ \vdots & \ddots & \vdots \\ D_{j1} & \cdots & D_{jj} \end{bmatrix} \cdot \frac{\partial^2}{\partial x^2} \begin{bmatrix} C_1 \\ \vdots \\ C_j \\ \vdots \\ C_n \end{bmatrix}, \quad (4)$$

where x is the relevant distance. When diffusion coefficients and concentrations are written in the form of two matrices, $\mathcal{D}$ and $\mathcal{C}$, respectively, Eq. (4) is expressed in a more compact manner as

$$\frac{\partial \mathcal{C}}{\partial t} = \mathcal{D} \cdot \frac{\partial^2 \mathcal{C}}{\partial x^2}. \quad (5)$$

Each of the coefficients of $\mathcal{D}$ characterizes the influence of a component j on the flux of component i . Because there are only $n - 1$ independent components, these coefficients constitute all together an $(n - 1) \times (n - 1)$ matrix where D_{ij} is not necessarily equal to D_{ji} . As for the n th component, it is often termed *dependent* because its concentration is determined from the others through mass conservation. For convenience, it is usually chosen among the slowest diffusing components. In oxide melts, network-forming cations (Si, Al, Ge, etc.) fit this definition since their diffusivity contrast with network-modifying cations considerably increases with decreasing temperatures.

2.2 Experimental Strategy

Any experimental approach has to be carefully designed to quantify diffusion timescales and chemical paths in a multicomponent system. Obviously, *tracer diffusion* experiments are of limited help because they do not reveal the complex coupling that may exist between the components of a system. Hence, it is necessary to investigate instead interdiffusion between two *end-member* melts whose overall compositions differ significantly, but not too widely; otherwise, Fick's formalism might not hold true any longer because of the dependence of diffusion coefficients upon bulk composition. In practice, gradients must be limited to a few wt % across the whole sample.

In addition, caution must of course be taken to use inert containers, to avoid devitrification upon reheating of the assemblage, to check the stability of the interface between the two end-members, and, in particular, to make sure that convective transport does not take place as it would dramatically change the timescale of melt homogenization. Therefore, at least a crude knowledge of the rheology and density of the two end-members is needed. To avoid convective transport, which is not always easy to

identify, a confining pressure on the assemblage may be applied with devices such as the piston-cylinder apparatus (e.g. [3]). Generally, however, it is more straightforward to put the densest glass at the bottom of the assemblage and to analyze the concentration of an added colored or isotopic tracer for ascertaining the lack of convection.

The number of experiments required to determine a diffusion matrix is also a key parameter that may temper the motivation of experimentalists. If the melt contains n components, then at least $n - 1$ independent concentration profiles must be measured [4]. Typically, the glasses juxtaposed to make the diffusion couple are selected symmetrically in compositional space relative to the target composition. Ideally, these diffusion profiles should not only intersect at the composition of interest but their eigenvectors should be colinear to in the eigenspace of the diffusion matrix [5]. The obvious difficulty in this respect is that these eigenvectors are generally unknown a priori. As a consequence, diffusion couples should be chosen, in the classical compositional frame, so that at least one component has a constant concentration. Finally, a conservative approach consists in making at least $2n$ experiments, with at least n independent diffusion couples and two different run durations in order to check the self-consistency of the data set [6].

3 Tracer vs. Chemical Diffusion

Extensive work by Liang et al. on the $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system [3, 7–9] illustrates well the fundamental differences between self- and chemical diffusion (Figure 1). In the former, calcium moves almost 10 and 5 times faster than silicon and aluminum, respectively. At constant Al_2O_3 concentration, calcium diffuses in contrast more slowly and silicon faster than their respective isotopes in the absence of chemical-concentration gradients (Figure 1). In other words, the two fluxes have become strongly correlated.

This process has long been known for both molecular and ionic fluids. In binary molecular and metallic fluids in a fixed-volume frame, the mobility of atoms is strongly constrained by the fact that local volume changes are forbidden. This constraint of no net volume flux is accounted for by the formalism developed by Darken [10] for thermodynamically ideal systems:

$$D = X_2 D_1^* + X_1 D_2^*, \quad (6)$$

where D is the chemical diffusion coefficient, X_i is the mole fraction of component i , and D_i^* is its self-diffusion coefficient. For ionic (or electrolytic) fluids, electroneutrality must be conserved. Since local charge buildup is forbidden, Coulombic interactions are the main restoring

Figure 1 Differences in CaO and SiO_2 concentration profiles between self- (a) and interdiffusion (b) experiments on a calcium aluminosilicate melt [3, 7]. Normalized concentration profiles of CaO and SiO_2 produced during two distinct diffusion experiments. (a) Self-diffusion traced by isotopes, and (b) chemical diffusion of the two oxide components in a ternary melt (CAS). Experiments were performed on compositionally comparable melts at 1500°C . Source: Data from [3, 7].

force. The flux rates of diffusing species then couple under the condition of no net flux of electrical charges. For the interdiffusion of two cations (or anions) present in a binary solution, one can define in this case a mean diffusion coefficient representing a weighted mean of the self-diffusion coefficients. Buck [11], for instance, proposed the expression

$$D = \frac{D_1^* D_2^* (z_1^2 X_1 + z_2^2 X_2)}{z_1^2 X_1 D_1^* + z_2^2 X_2 D_2^*}, \quad (7)$$

where z_i is the electrical charge of ion i . As it should, Eq. (7) satisfies the limiting condition that, at infinite dilution of one of the two ions, its self- (or tracer-) diffusion controls the overall chemical diffusion in the solution. From Eqs. (6) and (7), it also follows that the long range of Coulombic forces causes the slower ion to impede the displacement of the faster one more effectively than forces due to volume changes. Other things being equal, interdiffusion would thus be slower for ions than for non-charged particles.

4 Diffusion in Multicomponent Systems

4.1 A First Approach: The Effective Binary Diffusion

In a multicomponent system, diffusive fluxes interfere in a similar though more complicated way because of the multiplicity of concentration gradients. Although the various components tend to diffuse at different rates according to their own self-diffusivity, the lack of both net volume flux and electrical charge buildup strongly constrains the overall diffusion timescale and path. To take care of this complexity, Cooper [12] introduced the simplest approach of *effective binary diffusion* whereby the multicomponent melt is treated as a pseudo-binary system in which the component of interest is taken as the *solute* and all other components are taken together as the *solvent*. The flux of the component of interest then takes the simple form given by Eq. (1) with an effective binary diffusion coefficient (EBDC) that integrates all coupling effects.

As a result, the EBDCs are in general not constant for a given diffusion couple and they also depend on the direction of diffusion in the composition space [13]. In CaO–Al₂O₃–SiO₂ melts [7], the measured EBDC of SiO₂ at constant viscosity is, for instance, almost 10 times lower for diffusion at constant CaO than at constant Al₂O₃ concentrations. Another important feature of effective binary diffusion is that they vary with time at a fixed position in a given diffusion couple [14]. Hence, the composition, time, and geometry dependences of

EBDCs further complicate applications of these parameters to systems different from those for which they have been determined. In general terms, EBDCs and D s are indeed different for a given component across a given diffusion couple. In spite of their complexity, their mutual relationships have been worked out [13] without making it possible, however, to account for the critical phenomenon of uphill diffusion. In summary, determinations of EBDCs do not help much to predict the general diffusion processes taking place in a multicomponent system. A more fundamental approach is needed.

4.2 The Fick–Onsager Thermodynamic Approach

In Onsager's [2] formulation of Fick's laws, equilibrium is attained when the concentrations of the n components are equal across the system, which correspond to the state of maximum entropy. But gradients in chemical potential, and not in concentrations, are the true driving force for diffusion since the whole process eventually leads to a minimum Gibbs free energy. Rather than in terms of observed compositional gradients, the flux of a given component i is, strictly speaking, better written as

$$J_i = -\sum_j L_{ij} \cdot \frac{\partial \mu_j}{\partial x}, \quad (8)$$

where μ_j is the chemical potential of component j and the L_{ij} are *Onsager's diffusion coefficients* forming the symmetric kinetic matrix $\mathcal{L}$. To relate these chemical potentials to the chemical compositions, which are actually measured, one simply can relate the $\mathcal{L}$ and $\mathcal{D}$ matrices with

$$\mathcal{D} = \mathcal{L}\mathcal{G}, \quad (9)$$

where $\mathcal{G}$ is another matrix that accounts for the thermodynamic mixing properties whose elements, G_{ij} , are given by

$$G_{ij} = \frac{\partial(\mu_i - \mu_n)}{\partial X}. \quad (10)$$

Referring to [8] for a summary of the mathematical properties of these matrices, we will limit ourselves here to mention briefly information on microscopic interactions between the melt components that can be drawn from this formalism when use is also made of models relating chemical diffusion to self-diffusion coefficients. In practice, $\mathcal{L}$ can be derived if $\mathcal{D}$ and $\mathcal{G}$ are known. With an extension of the Darken-type Eq. (6) and the Nernst–Planck-type Eq. (7) to multicomponent systems, Liang et al. [8], for instance, found that the diagonal terms of the $\mathcal{L}$ matrix represent the intrinsic mobility of each component whereas the off-diagonal terms contain

information on both volume relaxation and ionic interactions. The $\mathcal{G}$ matrix could itself be expressed as a product of $\mathcal{F}$ and $\mathcal{N}$ matrices, the former essentially reflecting the thermodynamic nonideality of the solution and the latter the partial molar volumes of the components. Modeling in this way their experimental data set for the ternary CaO–Al₂O₃–SiO₂ system [7], Liang et al. [8] demonstrated that kinetic interactions (volume relaxation and ionic interactions), partial molar volume changes, and thermodynamic nonideality all contributed significantly to the coupling between diffusing components so that none of these factors could be neglected.

4.3 Determination of the Diffusion Matrix

Once the set of $(n - 1)$ components defining the $(n - 1) \times (n - 1)$ diffusion matrix $\mathcal{D}$ has been selected, several techniques exist to obtain the coefficients of the diffusion matrix from a set of diffusion experiments between different end-members. Their common underlying principles are fits of theoretical predictions obtained with the sought-after diffusion matrix to experimental diffusion profiles (or other functions derived from them).

At a time when computational power was limited, the Boltzmann–Matano method [14] was favored in early interdiffusion studies. It was originally developed to investigate concentration-dependent diffusion in binary systems. It consists in first transforming Fick's law (a partial differential equation) into an ordinary differential equation through a Boltzmann transformation in terms of the rescaled variable $\xi = x/2\sqrt{t}$. The new form can then be solved numerically so that the coefficients of the diffusion matrix become the solutions of a linear system of such equations. Therefore, at least as many independent profiles as coefficients must be obtained to solve this linear system.

One advantage of the Boltzmann–Matano method is that a unique solution actually exists, which can be readily obtained from experimental concentration profiles. The method requires to compute the spatial integral of the concentration profiles, however, so that experimental errors accumulate and degrade the accuracy with which the diffusion matrix is computed. The standard χ^2 method relying on least-squares minimization of the differences between experimental and calculated profiles may alternatively be used.

For complex systems, minimizing the error is most conveniently done on the basis of the eigenvectors of the diffusion matrix, that is, along directions in the composition space that remain invariant in the course of the diffusion process. Let us define

$$\mathcal{D} = \mathcal{P}\mathcal{A}\mathcal{P}^{-1}, \quad (11)$$

where Λ is the diagonal matrix of eigenvalues λ_i and $\mathcal{P} = (\mathbf{v}_1, \dots, \mathbf{v}_{n-1})$ is the matrix of the eigenvectors $\mathbf{v}_i$. Each λ_i represents a diffusion coefficient associated with an eigenvector $\mathbf{v}_i$. The coefficients of $\mathbf{v}_i$ characterize the proportions of the species exchanged in the corresponding diffusion mechanism. Denoting by $\mathcal{C}$ the concentration vector on the basis of the eigenvectors (a linear combination of the concentrations of the different oxides), one obtains the equation

$$\frac{\partial \mathcal{C}}{\partial t} = \Lambda \cdot \frac{\partial^2 \tilde{\mathcal{C}}}{\partial x^2}. \quad (12)$$

Since Λ is a diagonal matrix, this expression represents a set of independent equations whose analytical solutions are similar to that obtained for the diffusion of a single species. They can thus be readily adjusted to the experimental profiles $\mathcal{C}$.

With a number $(n - 1)^2$ of coefficients to be determined, the complexity of the optimization process rapidly increases with n so that it is important to check that the true χ^2 minimum has been found. If so, the same solution must, for instance, be obtained with differing sets of starting parameters for the χ^2 minimization. To derive such starting values, one can use first the Boltzmann–Matano method or, more simply, select literature data. In any case, a successful initialization can be achieved from visual adjustments of literature data or of the new experimental results.

Because of measurement errors, it is of course recommended to overconstrain the optimization problem with more diffusion experiments than the bare minimum $n - 1$ to improve the accuracy of the diffusion matrix [6]. Typically, noise can be a critical impediment when the diffusion matrix is ill-conditioned because of the coexistence of several diffusion mechanisms (corresponding to several eigenvectors) with very different eigenvalues. In such a case, small experimental errors have dramatic consequences on the minor eigenvectors (with smaller eigenvalues) even though the dominant eigenvectors are not so badly affected.

4.4 Uphill Diffusion

The ultimate manifestation of diffusive coupling in a multicomponent system is the particularly striking *uphill* diffusion of a component against its own concentration gradient. This effect can be understood only with the Fick–Onsager equations. Uphill diffusion of an element i typically occurs when off-diagonal terms of the diffusion matrix and concentration gradients of several components j are large. In this situation, the diffusive flux of i resulting from its higher concentration is overwhelmed by the effects of the off-diagonal coupling terms.

Figure 2 Uphill diffusion of CaO in the concentration profiles collected during chemical diffusion in the NCAS quaternary system at 1200 °C for one hour [6].

The initial concentration gradients then locally increase during diffusion (Figure 2). Since all compositional gradients have been erased at equilibrium, the phenomenon is necessarily transient but it is nonetheless important because it considerably affects melt homogenization. An intuitive way to understand this process is to view a component as “dragged along” by other components. This picture may be misleading, however, in that, the true driving force for diffusion is the chemical potential gradient. Consequently, if activity gradients are plotted instead of concentration gradients, then the anomalous uphill profile disappears because all components are actually going down their own gradients in the thermodynamic (activity) space (Figure 3).

4.5 Diffusion Path

From a theoretical standpoint, the thermodynamic description given by Eqs. (8) and (9) in addition provides one with interesting insights onto the diffusion and thermochemical pathways followed by the system in the

compositional space. A graphical view of chemical diffusion and of the couplings that characterize it is obtained with plots of chemical compositions along diffusion profiles (Figure 4). As long as the assumption of a semi-infinite medium is valid, the two end-members of the diffusion couple are then easy to show. The composition of the interface also lies along a straight line joining these end-members and represents their average composition. This plot is called a *diffusion path* because it displays the composition-time trajectory followed by any point of space (as long as diffusion has not reached the boundaries of the sample). In the absence of coupling between the components, all compositions plot along the straight line joining the end-members (Figure 4). Conversely, when diffusive coupling is significant, the trajectory is not a straight line but takes a symmetrical S-shape when the diffusion matrix does not depend on concentration (Figure 4).

This view is also of interest because it graphically represents eigenvalues and eigenvectors of the diffusion matrix $\mathcal{D}$ [4]. Typically, the two coplanar vectors determining the orientation of the S-shaped diffusion path are the eigenvectors of $\mathcal{D}$. Furthermore, the diffusion path close to the end-member compositions is colinear with the major eigenvectors (i.e. those with the largest eigenvalue) because the fastest exchange process will dominate during the early stages of diffusion. On the diffusion path, this fast reaction will thus dominate for compositions close to the end-members (Figure 4). The plot of the diffusion path is, therefore, a simple way to identify the exchange reactions at work during chemical diffusion.

5 Available Chemical Diffusion Data

5.1 Identified Couplings

Experimental determinations of the diffusion matrix are few for multicomponent oxide systems. A comprehensive discussion of the published data can be found in [15] for

Figure 3 Diffusion profiles of Figure 2 represented in the activity space, no longer showing uphill diffusion [6]. Activities calculated with the FactSage thermodynamic program (Chapter 5.3) and rescaled to fit on the same figure ($\times 10^9$ for Na₂O, $\times 10^5$ for Al₂O₃, and $\times 10^4$ for CaO).

Figure 4 Diffusion paths viewed in 3-D around a single melt composition in the NCAS quaternary system [6]. (a) Diffusion of Na_2O versus CaO , essentially controlled by only one exchange reaction, represented by the large red arrow. (b) Diffusion of Na_2O versus Al_2O_3 , controlled by two exchange reactions represented by the thin and bold vectors indicated, respectively.

binary systems and in [14] for diffusion matrices. The ternaries $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (CAS) and $\text{MgO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (MAS) and the quaternary $\text{CaO}-\text{MgO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (CMAS) are relatively well-characterized systems because they contain key components of natural and industrial melts and glasses. Despite the relatively inconsistent nature of the earliest studies [16–19], some common features are observed. As expected, chemical diffusion in molten CAS, MAS, and CMAS shows clearly diffusive couplings among the oxide components (uphill diffusion profiles). This coupled chemical diffusion between CaO and SiO_2 and MgO and SiO_2 makes their respective diffusion distances comparable to one another (e.g. [20]; 7).

In general, large concentration gradients in alkaline-earth oxides accelerate the counter-diffusion of SiO_2 (Figure 1), whereas the nature of the coupling depends markedly on melt composition. Typically, the flux of SiO_2 is strongly coupled to the concentration gradients of CaO and MgO in polymerized melts. On the other hand, the flux of Al_2O_3 is preferentially coupled to the concentration gradients of CaO and MgO in depolymerized melts. Furthermore, the sign of the coupling of CaO and MgO with either Al_2O_3 or SiO_2 reverses between polymerized and depolymerized compositions. The fluxes of CaO and MgO are positively coupled to the concentration gradients of SiO_2 in siliceous compositions, whereas they are negatively correlated in silica-poor compositions. Finally, it is generally observed that the diffusive behaviors of CaO , FeO , and MgO are very similar in a given melt [14, 21]. It is thus reasonable to consider $\text{CaO} + \text{MgO} + \text{FeO}$ as a single component in the absence of a complete diffusion matrix.

Chemical diffusion of alkali cations has also been studied in various systems such as $\text{K}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (KAS), $\text{K}_2\text{O}-\text{Na}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2-\text{H}_2\text{O}$, $\text{K}_2\text{O}-\text{SrO}-\text{SiO}_2$, $\text{Na}_2\text{O}-\text{CaO}-\text{SiO}_2$ (NCS), and $\text{Na}_2\text{O}-\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (NCAS) [6, 21–25]. As for alkaline-earth-bearing

systems, the experiments point to significant coupling. The diffusive flux of Na_2O is strongly and negatively coupled to the concentration gradients of SiO_2 and CaO . Interestingly, in the quaternary $\text{Na}_2\text{O}-\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system, Na_2O is primarily coupled to CaO and mainly decoupled from the motion of network formers [6]. Turning to the flux of K_2O , it seems moderately to weakly coupled to the gradients of SiO_2 . Again, the silica content has a strong control on the sign of the coupling. The diffusive flux of SiO_2 is only weakly coupled to the concentration gradients of Na_2O in basaltic (silica-poor) melts, but strongly and negatively coupled to the concentration gradients of the alkalis in silica-rich melts. Finally, the diffusion experiments of [25] also suggest that the diffusive behavior of water in multicomponent liquids is similar to that of Na_2O : the diffusive flux of water is negatively and strongly coupled to the concentration gradients of silica.

A direct comparison between the magnitude of the eigenvalues of the diffusion matrices in alkali- and alkaline-earth-bearing simple systems is greatly hampered by the limited data sets available. At a given temperature, it nonetheless seems that eigenvalues are from 1 to 4 orders of magnitude higher in molten CAS, CMAS, and MAS than in KAS. This is consistent with the tighter bonding of tetrahedral aluminum with potassium than with calcium and magnesium as charge-compensating cations, which thus results in an overall lower mobility of potassium [14].

5.2 Diffusion Paths

As noted in [24], each eigenvector of the diffusion matrix can formally be written as an exchange reaction between species, the coefficients of the eigenvectors determining the stoichiometry of the reaction. For example, in the CAS system, an eigenvector of coefficients (1, -0.5 , -0.5) in the basis $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ is equivalent to the reaction

This reaction is consistently found in various compositions of the CAS, MAS, and CMAS systems [7, 19], suggesting that alkaline earth elements move through the aluminosilicate network by breaking $\text{Al}-\text{O}-\text{Si}$ linkages. Such microscopic insights on diffusion mechanisms demonstrate the power of the diffusion-matrix approach: with an appropriate mathematical apparatus, exchange reactions at the microscopic level can be obtained from macroscopic measurements of concentration profiles. Another major reaction has been identified in the NCS and NCAS systems, namely, the exchange of sodium and calcium (e.g. [5, 6]). It probably takes place in the modifier-rich channels described by Greaves

(Chapter 2.5), which represent preferential migration pathways for these cations. Because this migration does not involve the breaking of bonds formed between oxygen and network formers, the eigenvalue of the exchange of sodium and calcium is significantly larger than those of reactions involving network formers.

Interestingly, the diffusion matrices obtained in quaternary systems [6, 19] suggest that exchange reactions of simple (i.e. ternary) systems can often be transposed to more complex systems. Such results are consistent with the essentially pairwise nature of interatomic potentials (Chapter 2.8) and, thus, with the fact that eigenvectors point to the collective rearrangements that dominate mass transport (because a given mechanism will be faster and energetically more favorable than others). Nonetheless, several questions remain open about the interpretation of eigenvectors in terms of exchange mechanisms, such as why eigenvectors vary or not when composition changes.

5.3 Temperature Dependence

The temperature dependence of the elements of diffusion matrices has received less attention. The available data focus on the CAS, CMAS, and KAS systems [9, 14, 16, 24], but they have unambiguously shown that the eigenvalues obey simple Arrhenius laws. Even though these eigenvalues vary with composition by more than five orders of magnitude at a given temperature in the CAS system, the activation energies are relatively constant at around 200–220 kJ/mol. These values are also very close to the activation energies for the self-diffusions of Si and Ca in similar melts (e.g. [3, 7, 16, 17]) and to the typical activation energies for viscous flow (Chapter 4.3). The temperature dependence of the $\mathcal{D}$ eigenvalues in the KAS system is more complicated. In that case, the activation energies of the two eigenvalues are very different. This feature likely highlights the fact that SiO₂ and CaO are strongly coupled in CAS. On the contrary, in the KAS system, the diffusive flux of K₂O is less coupled to the concentration gradient of SiO₂.

Turning finally to the eigenvectors of the diffusion matrices at a given melt composition, we note that they do not seem to be very sensitive to temperature. This near constancy may thus suggest that diffusion paths persist over large temperature intervals. If true, this observation would make a systematic survey of these paths even more important to develop an empirical and practical description of chemical diffusion in multicomponent melts.

6 Perspectives

Modeling of multicomponent diffusion will greatly benefit from a better description of the activity–composition relations in molten systems. Improved thermochemical

descriptions of melts will certainly help to describe molecular interactions at the origin of uphill diffusion. Before such a comprehensive approach is available, however, a reasonable set of experiments focused on a few important quaternary systems should assess the persistence of eigenvectors over a wide range of compositions, temperature, and pressure. This would be a major achievement because available data suggest that vectors defined for simple systems are preserved when additional components are added. Since these eigenvectors are related to local exchange reactions, their persistence would clearly help bridging the gap between structural and kinetic aspects of glass-making melts. The signatures of these reactions could then be probed either by molecular dynamics or first-principle simulations. In addition, in a near future, the exchange rates computed from *in situ* NMR measurements could be compared with the characteristic kinetics of such local reactions to assess the overall self-consistency of the structural and kinetic models.

Acknowledgments

We thank C. Claireaux for the outstanding experimental work performed during her PhD and for sharing with us some unpublished data. The thoughtful comments provided by M.J. Toplis and H.C. Watson allowed us to improve greatly the readability and the conciseness of this chapter.

4.5

Thermal Diffusivity and Conductivity of Glasses and Melts

Anne Hofmeister¹ and Alan Whittington²

¹ Department of Earth and Planetary Sciences, Washington University, St. Louis, MO, USA

² Geological Sciences, University of Texas at San Antonio, TX, USA

1 Introduction

The rate at which heat moves through a glass has fundamental implications in both industry and geology. In glassmaking, for instance, thermal conductivity controls the rate at which flat (Chapter 1.4) or hollow (Chapter 1.5) glass is shaped at high temperature. In geology, it determines the rate of cooling of ascending magma, the longevity of magma chambers, and the extent of welding by which glassy volcanic ash gives rise to dense rock (Chapter 7.2). Because the rate of heat transfer within a phase is characterized by its thermal conductivity (k) and thermal diffusivity (D), these properties need to be known as a function of temperature and chemical composition if heat transfer is to be understood in a quantitative way in a variety of fundamental or applied contexts.

Over a microscopic scale, thermal energy is transferred via either *conduction* or *radiation* in response to an imposed thermal gradient. Heat can also be transported by *advection* where moving mass elements of a body each carry heat according to their heat capacity and temperatures. The macroscopic process of *convection* combines conduction, radiation, and advection, so it constitutes a system-wide response achieved under particular conditions rather than a fundamentally different heat-transfer mechanism.

To decipher the complex process of heat transfer, the first step is, therefore, to examine the two basic processes of conduction and radiation. This will be done at the beginning of this chapter where particular emphasis will be placed to define rigorously both processes and to review their microscopic origin. We will then describe in some detail how heat-transport properties are

measured because of the possible experimental pitfalls that have caused confusion in the literature. Finally, we will review the aforementioned temperature and composition dependences of these properties and point out some correlations they show with other physical properties of glasses and melts.

2 Theory

2.1 Thermal Conductivity and Diffusivity

The thermal conductivity (k) of a body relates temperature (T) and heat flux (F) by Fourier's law:

$$F = -k \nabla T. \quad (1)$$

For heat conduction in an isotropic medium under isobaric conditions, one has

$$\rho C_p \frac{\partial T}{\partial t} = k \nabla^2 T + Q + \frac{\partial k}{\partial T} \left[\left(\frac{\partial T}{\partial x} \right)^2 + \left(\frac{\partial T}{\partial y} \right)^2 + \left(\frac{\partial T}{\partial z} \right)^2 \right]. \quad (2)$$

where ρ is the density of the body, C_p its heat capacity at constant pressure (P), and t time and Q describes internal heat sources such as radioactivity or viscous heating. The nonlinear form of Eq. (2) provides feedback between k and T because k depends on temperature in a complex way.

With some techniques one measures instead the thermal diffusivity, from which k can be determined from the definition

$$k_{\text{lat}} = \rho C_p D, \quad (3)$$

where C_p and ρ are generally available or can be estimated with reasonable accuracy (see Chapters 3.5 and 3.6). Historically, the focus has been on k , which is complex

Reviewers: D. Cahill, University of Illinois, Urbana Champaign, IL, USA
F. Spera, Earth Science, University of California, Santa Barbara, CA, USA

compared with D , because heat capacity depends strongly and in a complicated manner on T . Over a temperature range sufficiently narrow that the physical properties are effectively constant, if Q is zero, then Eq. (2) takes on a simple form whereby thermal diffusivity alone governs the temperature–time evolution:

$$\frac{\partial T}{\partial t} = D \nabla^2 T. \quad (4)$$

2.2 Conductive Heat Transport

Below about 800 K, the transfer of heat from or to a body is governed predominantly by conduction if one neglects transient thermal events and the experimental difficulties associated with the high transparency of glasses. In an electrically insulating solid, the so-called lattice conductivity (k_{lat}) has been considered to be the main mechanism, involving scattering of *phonons* (Figure 1, top), which are quantized lattice vibrations ($k_{\text{ph,sc}}$). Over unit-cell distances, their characteristic speed is similar to the velocity of sound in the body. At low temperature (<30 K), the thermal conductivity of glasses is modeled in the same manner as for crystals wherein phonon scattering models are based on Debye’s concept of the phonon gas. Because different variations of k with T are observed for crystals and glasses at higher temperatures, however, existing models have considered that different mechanisms operate in disordered glasses [1]. However, the temperature dependences of D for glasses and crystals are similar up to the glass transition temperature [2], and thus the “glass-like” behavior, where k increases from cryogenic temperatures up to a plateau, results from the strong increase in heat capacity with T that overwhelms the weak decrease in D as T increases (Eq. (3); data

provided below) and not necessarily from a different mechanism.

The lattice thermal conductivity in phenomenological models is calculated from

$$k_{\text{lat}} = \frac{1}{3} \rho C_V u \Lambda, \quad (5)$$

where C_V is the isochoric heat capacity, u is the velocity of phonons or elastic waves, and $\Lambda = \tau u$ is the mean free path of phonons with a mean lifetime τ . The concept originated with Debye, but the estimation of phonon lifetimes or mean free paths remains the most uncertain part of the modeling.

For glassy materials, the plateau in k has been modeled with the assumption that the harmonic motions of neighboring atoms are uncorrelated. Einstein’s model of vibrations in solids has been found adequate for a variety of complex glasses [1]; however, its underlying assumption, i.e. that no coherence exists between motions of neighboring atoms, is questionable. Other phenomenological models concern scattering from two-level states and tunneling. Owing to uncertainties in phenomenological models, C_p is often substituted for C_V in order to make use of measured properties in the computation.

To describe the change of k with temperature, more complex, first-principles models are currently used. Both the Kubo–Greenwood approximation and molecular dynamics have been applied to amorphous Si (see summary by Lee et al. [3]). The former involves calculation of the heat currents (fluxes) between harmonic states when thermal energy and thus temperature vary through changes in vibrational quantum numbers. With molecular dynamics (Chapter 2.8), one can explicitly incorporate anharmonicity and specifically account for temperature-dependent structural changes.

Recently, Hofmeister et al. [2] have proposed that an additional mechanism exists, wherein heat is diffused radiatively at infrared frequencies but at slow phononic speeds by bulk phonon polaritons. This mechanism is manifest in experimental data at high temperature wherein D increases with T for both crystals and glasses. For further discussion and a new model see [4].

Figure 1 Schematic of radiative transfer. Thick black arrows show the entry of heat from the source into a sample (shaded to depict a temperature gradient). Top, phonon diffusion. Middle, radiative diffusion requires that light is attenuated over small distances. Bottom, ballistic, or direct radiative transfer, which bypasses the sample, is commonplace in experiments on transparent glasses.

2.3 Radiative Heat Transport

2.3.1 Absorbance

From temperatures higher than about 700–1000 K, a distinct heat-transfer process begins to operate, involving high-frequency photons, and rapidly predominates if the material is transparent (see [5]). Distinguishing such photonic from phononic processes is important because the former is not always a material property as radiative transfer between two bodies depends not only on frequency, temperature, and attenuation of light but also

on the distance involved, over which temperature may change significantly.

When the distance over which the temperature changes significantly is larger than the distance over which light becomes attenuated, heat diffuses radiatively via progressive absorption and re-emission of photons. The process then is represented by an effective thermal conductivity, $k_{\text{rad,dif}}$ (Figure 1, middle), which is calculated from optical spectra, generally with the simplifying assumption of constant sample absorbance. Because diffusion at high frequencies generally requires larger distances than are realized during laboratory measurements of k or D , this phenomenon is limited to geologic processes or to large vats of glass.

Absorbance is the key parameter when dealing with diffusion of radiation. It is defined by

$$a = AL = -\ln\left(\frac{I_{\text{trans}}}{I_{\text{incident}}}\right), \quad (6)$$

where A is the absorption coefficient, L the thickness of the material, and I_{trans} the light transmitted (not including reflection losses), which is measured with respect to I_{incident} , the light entering the crystal. “Optically thick” conditions generally hold if the absorbance is greater than 2 but not so large that the medium is opaque (i.e. that some small amount of light exits the sample). For heat-transport problems, an additional stipulation is that the distance over which temperature changes is large compared with the distance required for optically thick conditions (Figure 1, middle). Diffusive conditions thus exclude direct or ballistic radiative transfer, which occurs under optically thin conditions of $AL < 1$, and when light crosses large temperature differences (i.e. ~ 4 K over the $\sim$ mm distances in laser-flash experiments) (Figure 1, bottom).

2.3.2 Diffusive Radiative Transport

Derivations of the effective thermal conductivity ($k_{\text{rad,dif}}$) associated with an optically thick, nonopaque medium in local radiative equilibrium trace back to Kellett’s [6] attempts to understand heat transport in glass furnaces. Kellett [6] and subsequent workers assumed that light enters the solid as a point, forming a cone of diffracted radiation. Instead, entry occurs across a planar surface, and in view of the second law of thermodynamics, heat transfer only occurs down the thermal gradient, and so the historical work includes an erroneous factor of n^2 , where n is the index of refraction, in the effective thermal conductivity. Correcting for this error gives

$$k_{\text{rad,dif}} = \frac{16\sigma T^3}{3A}, \quad (7)$$

where σ is the Stefan–Boltzmann constant. Although this equation is not correct in detail for other reasons, it does

show that radiative effects are most important at high temperature. Importantly, Eq. (7) requires that the absorption coefficient be independent of frequency and temperature (see summary by Choudhary and Potter [7] and the revised model in [4]).

Neither optically thick conditions nor constant absorbance applies to glasses. Experimentally, silicate glasses are optically thick only in the infrared and ultraviolet. Obviously, colorless glasses are transparent in the visible, and this high transparency extends downward in frequency to just above the infrared (the near-IR). Similarly, colored glasses (Chapter 6.2) are commonly transparent in the near-IR. This problem of low A occurring in certain spectral regions creates extremely large values of $k_{\text{rad,dif}}$ so some average of A is used instead. Commonly the Rosseland mean absorption coefficient is used, which is weighted using Planck’s blackbody function:

$$I_{\text{bb}}(\nu) = \frac{2h\nu^3}{c^2} \left[\frac{1}{\exp(h\nu/k_B T) - 1} \right]. \quad (8)$$

where h is Planck’s constant, ν frequency, c the speed of light, and k_B Boltzmann’s constant. However, the Rosseland formalism does not address the underlying issue that glasses are not optically thick in certain frequency regions, which in turn means that radiation is *not* diffused but carried ballistically (see Section 2.3.3). Although more precise formulations than Eq. (7) exist, they are not commonly applied because they require specific knowledge of A from infrared to ultraviolet frequencies for the glass of interest (see Choudhary and Potter [7] for a summary of absorption data and a discussion of the problems). The same fundamental problem exists in the more precise formulations, namely, that A being near zero in any frequency range violates the diffusive approximation, and so the formulation is not relevant.

2.3.3 Ballistic Radiative Transport

Neither Eq. (7) nor its more precise alternatives address properly the problem of transparency of glasses in laboratory experiments. When temperature gradients are steep, light from the source can warm the measuring thermocouple with scant participation of the medium (Figure 1, bottom). This process is termed boundary-to-boundary, direct, or ballistic and is especially important in transient experiments where radiative transfer dominates the initial response of the system to the input of heat because of the tremendous speed of light.

This ballistic radiative transfer takes place in *optically thin* samples and depends on the experimental conditions, whereas diffusive radiative transfer operates in *optically thick* samples and is a material property. Distinguishing the two processes can be difficult, however, because both are governed by Planck’s blackbody

function, so they can operate at the same time, and also because glasses are transparent at high frequencies over mm to cm scales. As a result, confusion between the two has led experimental data on solids to be often misinterpreted, both historically and recently, which has adversely affected our understanding of the thermal conductivity of glasses and melts.

A model of ballistic radiative transport for use in laser-flash analysis experiments provided by Hofmann et al. [8] is widely used in data analysis. Its details are beyond the scope of this chapter, but in essence its equations are fitted to the raw temperature–time data, permitting extraction of thermal diffusivity for small temperature differences, after Eq. (4). The model does not require knowing optical properties.

Other methods of measurement, particularly transient, are affected by ballistic radiative transport. No simple formula exists for optically thin conditions (Figure 1, bottom). In an attempt to remove radiative effects from the data, some researchers have reduced the total measured thermal conductivity by using equations intended to describe diffusive radiative transfer as described here and in Section 3. This approach can only provide a very rough estimate of ballistic radiative effects, with uncertainties exceeding a factor of 2.

2.4 Characteristic Speeds of Microscopic Mechanisms

All solutions to the temperature–time Eq. (4) have the form

$$D \sim L^2/t, \quad (9)$$

where t is a characteristic thermal timescale. Hence, a cooling front moves at a speed $u \sim L/t$. Inserting this approximation into Eq. (9), one then obtains

$$u \sim D/L; \quad (10)$$

so, over short scales, the speed u is that of a disturbance, namely, the compressional velocity (u_p) for conduction and c/n for high-frequency photons. The ratio of the speeds at any given distance holds for all length scales. Hence, the initial response of any system to a transient heat pulse is governed by high-frequency radiative transfer, which is $\sim 10^5$ times faster than conduction. Quasi-radiative equilibrium is rapidly attained, after which phononic conduction governs the temperature evolution.

This conclusion has important implications for heat-transfer experiments. During transient experiments, the time intervals involved are sufficiently short that ballistic radiative transfer has a large impact on the results

regardless of the actual temperature. For steady-state experiments, the slow cooling regime is reached, and so the effect of direct radiative transfer depends on the flux, which in turn depends strongly on the temperature in accord with Planck's function (Eq. 8). Thus, for cryogenic temperatures, steady-state experiments are less affected by direct radiative transfer.

3 Measurement Techniques

For measuring thermal transport properties, transient methods generally provide D , whereas steady-state variants yield k . Even though many such methods exist, we will deal with those that have been applied to glasses or are widely used and will also mention new developments that are promising for future glass research. Because the molten state is of particular interest, the focus will be on high-temperature (≥ 300 K) methods, whereas discussion of low-temperature measurements will be omitted. Absolute values are a concern because problems such as radiative transfer and contact losses differ with different techniques, which make it difficult to benchmark them. Owing to the experimental difficulties and inconsistencies in the data (especially at high temperature), we aim at providing enough details such that the potential shortcomings of each method can be understood. For a thorough analysis, see [4].

3.1 Contact-Free Methods

Laser-flash analysis [9] is commonly applied to diverse materials. For glasses it is advantageous because contact losses are absent and ballistic radiative transfer associated with sample transparency can be removed with the model of Hofmann et al. [8].

A sample in the form of a small, thin slab (~ 0.3 – 3 mm thick by 6 – 15 mm diameter) is held at temperature in the furnace (Figure 2, inset). Additional heat is supplied remotely by an IR laser pulse to a thin graphite coating on the bottom of the slab. As the increment of heat migrates to the top of the sample, which is also graphite coated, the surface temperature of the slab rises, and its emission increase is recorded by the IR detector (Figure 2). The detector response is known as a temperature–time curve. Additional metal coatings (Au or Pt) beneath the graphite can be used to suppress radiative transfer, but they tend to perturb the measurement for materials such as glasses that have low D values [10].

For the simplest case of adiabatic heating, without any radiative heat transfer [9],

Figure 2 Time-temperature curves and schematic of LFA experiments. Gray curve: raw data for moldavite glass. Heavy arrow: laser pulse. Solid line: Hoffman et al.'s [8] model, with processes as indicated. (Inset) Physical transfer of heat during the experiment. Emissions (light arrows) from the top graphite coat are recorded by an infrared detector. After the laser pulse (heavy gray arrows) is absorbed by the bottom coat, this heat then either traverses the sample as photons (medium arrow) near light speed, c/n , or as phonons (squiggle arrow) near sound speed, u , both increasing emissions.

$$D = 0.1388 L^2 / t_{\text{half}}, \quad (11)$$

where L is sample thickness and t_{half} is half of the time required for temperature to reach the maximum after the laser pulse. In the absence of radiative transfer, the main uncertainties arise from sample thickness and deviations from truly planar and parallel faces. Experimental uncertainties of $\pm 2\%$ have been inferred for measurements of D_{lat} from benchmarking against graphite or iron. But graphite properties can vary from one sample to another, so the development of standards and round-robin testing is needed with homogeneous materials that are not transparent and thus can be accurately measured with other techniques.

At very high temperatures, data can be collected on suspended glass disks, even above the glass transition, until the sample viscosity becomes sufficiently low for flow or crystallization to occur [10, 11]. Thermal diffusivity of melts in containers has also been measured. In that case, however, overly large values have been obtained because available models of the time-temperature signal account either for radiative transfer or for the contribution of the finite thickness of the container, but not for both effects.

In a variation of the laser-flash method, the reflected signal from the base of a platinum crucible containing molten glass is analyzed, which essentially represents a thermoreflectance technique whose main advantage is that problems with bubble formation and retention are avoided. With this technique, Shibata et al. [12] studied Na-Ca-Si oxide glasses used as research standards for diverse properties. When interpreting the time-temperature curves, they did not account for ballistic radiative transfer, which does not seem to play a role in reflection experiments. Although they did not benchmark their method, their results are comparable with data on similar compositions measured with the standard LFA technique (Figure 3).

3.2 Conventional Techniques Involving Physical Contacts and Direct Heating

Except in recent work, most studies of $k(T)$ or $D(T)$ have utilized conventional techniques wherein a heat source and/or thermocouples directly contact the sample (see review [5] and also the data summarized by Choudhary and Potter [7]). Common features of contact methods are upper temperature limits of about ~ 1200 K, long measurement times, radiative heat losses from the surface, variable amounts of ballistic radiative transfer, and contact losses at the interfaces that cannot be avoided

Figure 3 Laser-flash analysis data on D of melts. Compositions in Table 1. Symbols with least squares fitted lines from Shibata et al. [12]. Lines without symbols are data in Hofmeister et al. [11] and references therein. Except for MFL, moldavite, and leucogranite with 1–2 wt % FeO, these glasses have negligible iron contents.

through surface polishing (see below). To determine k , steady-state methods are generally used, which require information on both the flux and the temperature gradient, Eq. (1); in addition, boundary conditions and sample geometry influence the results. Obtaining D involves transient methods wherein the time that a thermal disturbance takes to travel a certain distance is measured (Eq. 4). Some techniques provide both k and D . Examples are the transient hot-wire and hot strip methods, which have uncertainties of ± 6 and 30%, respectively.

Conventional measurements on hard crystalline solids commonly differ by $\pm 20\%$ even at room temperature. Data on glasses vary by a similar amount. Offsets existing between various data sets collected on similar materials by different authors are consistent up to 500–700 K, whereupon $\partial k/\partial T$ changes sign. Trends are less regular at higher temperatures. Both of these high-temperature discrepancies are due to variable amounts of unwanted, ballistic radiative transfer. Particulars of the experiments (e.g. contact adhesives, sample thickness, and absorption characteristics) are likely causes of the variation in the position and degree of the upturns in $k_{\text{meas}}(T)$. Radiative effects are reduced if absorption from the visible to near-IR is strong (e.g. glass with coloring dopants). Some researchers have attempted to separate phonon from photon components by subtracting $k_{\text{rad,dif}} \sim cT^3$ (or other approximations) from the measured k to obtain k_{lat} [5]. This approach is very approximate because optically thick conditions are difficult to achieve experimentally in the near-IR region, so the radiative transfer is not diffusive but ballistic and cannot be accounted for by Eq. (7). The correction is large even for darkly colored glasses [14].

An additional source of error arises from systematic losses that occur in conventional measurements because of the aforementioned thermal-contact resistance. This impediment can be described as a thermal resistance, r_{th} , which is the inverse of the thermal conductivity of the interface. Because thermal resistances in series add, one has

$$\frac{1}{k_{\text{meas}}} = \frac{1}{k_{\text{sample}}} + r_{\text{th}}. \quad (12)$$

So contact measurements set a lower limit on k measurements at 298 K in the absence of other problems. Rewriting Eq. (12) one obtains

$$D_{\text{meas}} \sim D_{\text{true}} / (1 + D_{\text{true}}/D_{\text{contact}}). \quad (13)$$

Copper with $D = 111 \text{ mm}^2/\text{s}$ is commonly used as a heating element. Because D of the contact is a blend of the two substances, it lies between D of the metal and that of insulator (i.e. D_{contact} is $\sim 50 \text{ mm}^2/\text{s}$), and the loss should be $\sim 10\%$ per contact.

3.3 Periodic Contact Techniques

This type of method involves application of a heat pulse to probe the immediate response of the system, which generally gives rise to strong ballistic radiative transfer. Ångström's method or its variants are widely used. In brief, a sinusoidal source of heat at frequency ω is applied to one end of a rod-shaped sample, and the phase of the decaying sinusoidal temperature wave that passes through the sample is measured at a distance L along the rod. Solutions to Fourier's equation in one dimension show that the phase depends on $L(\omega/2D)^{1/2}$. Correction terms address boundary conditions such as surface losses via radiation to the surroundings, but other errors stem from the presence of the smaller diameter thermocouple wire inserted in a hole drilled at the center of the sample. The hot-probe technique is similar, involving measuring the temperature rise created by a long linear heat source embedded in a medium.

The 3ω method (Cahill and Pohl [13]) involves a single contact. Thermal conductivity is determined below about 750 K with a third-harmonic detection scheme from the self-heating of a narrow metal line deposited on the sample. This radial method mixes two polarizations. An important advantage is insensitivity to blackbody radiation. Slightly lower values for silica are seen with the 3ω method than with laser flash (Figure 4), but this difference might alternatively be attributed to sample differences rather than to inconsistency between the methods.

Figure 4 Comparison of k for type I SiO_2 glass (slightly oxygen-deficient fused quartz with negligible water content) from radiation-free methods. Dotted line = LFA [10]. Solid line = 3ω technique [13].

3.4 Steady-state Contact Techniques

In steady-state experiments, such as the divided-bar method, radiative transfer should be unimportant. This is true at low temperature, but not at very high temperature where the high radiative heat flux makes quasi-radiative equilibrium difficult to achieve over the duration of experiments. Linear and radial geometries are used wherein the heater is separated from the receiving thermocouple.

3.5 Contact Techniques That Are Neither Transient, Periodic Nor Steady-state

An example is the glass-metal contact method ([14]), which has promise for molten materials. In this technique, a metal probe at a temperature different from that of the glass is inserted, and the coefficient of heat penetration = $kC_p\rho$ is determined directly from fits made to the asymptotic temperature jumps or drops recorded during the experiment. The method is relatively insensitive to radiative transfer. Although the results agree with LFA analyses for soda-lime glass of similar compositions, they show more scatter (Figure 5). Another example is the hot-wire method, which has been applied to slags [5, 15], as discussed below.

4 Thermal Diffusivity and Conductivity Data: Key Variables

Low-temperature heat transport studies of diverse glassy substances such as amorphous Si are found in the physics literature (cf. [1, 13]). Data at higher temperatures, mostly on silicate glasses, exist in the Earth and materials science articles [10, 11, 14], whereas results for the molten state, particularly Ca–Al slags, are found in engineering reports

Figure 5 Comparison of k at high temperature from LFA to contact techniques. Curves: soda-lime glasses [11] listed in Table 1. Diamonds show the uncertainty arising from thermal diffusivity measurements for one sample. Squares: data from Tempel et al. [14] with a metal probe technique on a glass that is similar to 1895. Vertical lines: glass transition temperatures from viscometry and in LFA experiments (see text).

[5, 7, 15]. We list data on D and k in Tables 1–3, with a focus on high-temperature results, namely, those obtained from room temperature to the glass transition and beyond, these selected data being representative of the range of chemical compositions and structures examined by LFA [10, 11, 16–18]. Purposely, we have limited ourselves to LFA studies of bulk samples from which radiative transfer effects have been removed to make direct comparison between sample properties. We will then take additional advantage of the fact that these

measurements involve glasses and melts of the same composition, which will permit another type of comparison to be made. Unfortunately, such measurements of glasses are limited to silicates. Other LFA measurements exist for borosilicate crown glass (*n*-BK7, which consists of 70 wt % SiO₂, with roughly equal amounts by weight of B, Na, and K oxides) and yielded $D(T)$ data similar to those of the other silicate and aluminosilicate glasses presented below. This similarity comes as no surprise, because crown glass is a silicate glass. Other types of glasses exist, such as those that are phosphate based, but heat-transport data has not been obtained from bulk samples for which radiative transfer effects have been

removed. Similarly, data on amorphous silicon is limited to thin films and to low temperatures and does not provide a good basis for comparison of chemical effects.

Before commenting on these results, however, we must briefly mention the effects of inclusions (including crystals and pores), water content, and internal strain because such defects are often present in the samples investigated. For pure silica glass, variations in thermal history and internal strain, for instance, strongly affect D (e.g. [10]), whereas higher water contents cause D_{glass} to decrease and make the glass transition to occur over wider temperature intervals and at lower temperatures. Owing to the importance of thermal history, a spread in D of about

5% occurs for any given chemical type of silica glass (e.g. with Cl or metal impurities). Studies of commercial soda-lime glasses of different ages have shown that greater variability is associated with antique than with modern glasses, which was attributed to inhomogeneities such as the presence of tiny bubbles and to variations in fictive temperature and internal strain induced by different annealing and/or quenching rates [11].

Inclusions, such as bubbles or crystals, have effects on thermal conductivity that can in principle be predicted from effective medium theory. However, an in-depth discussion of this theory and related approaches is beyond the scope of our report, and published applications largely concern crystalline materials. Of particular interest is the effect of bubbles that has not yet been quantified. Qualitatively, in samples with a milky appearance, a large number of bubbles should reduce radiative transfer as a result of scattering. Bubbles should also reduce phononic heat transport, by analogy to the effect of pores on D of crystalline materials. A simple, but not robust approach, is to use the analogy of electrical resistors in parallel:

$$D_{\text{total}} = \frac{1}{\frac{1-\phi}{D_{\text{glass}}} + \frac{\phi}{D_{\text{pores}}}}, \quad (14)$$

where ϕ is porosity. For the bubbles, the thermal diffusivity of water (0.14 mm²/s) can be used. Roughly, ~10% bubbles should then reduce D from 1 to 0.77 mm²/s.

4.1 Temperature Dependence of Thermal Diffusivity and Conductivity

As observed for diverse crystalline materials, e.g. [2], the thermal diffusivity of glasses continuously decreases with increasing temperature before becoming nearly constant at high temperatures (Figure 6). However, for some SiO₂-rich glasses, a slight increase of D with temperature is seen from ~1000 K up to the glass transition [10]. For samples with high Fe²⁺ contents, $\partial D/\partial T$ is distinctly positive above about 800 K (Figure 7). As discussed in Section 4.4, these positive slopes are not due to ballistic radiative transfer, which was removed with Hofmann et al.'s [8] model: its significance is discussed in Section 3.

Although the nominal uncertainty in the LFA technique is $\pm 2\%$, a wider spread is seen in D for repeat runs and runs on samples that should be identical chemically (e.g. albite glass in Table 2). Part of the variation could result either from sample differences or from experimental uncertainties (e.g. glasses must be very thin to avoid development of a thermal gradient greater than 4 K per mm, so Eq. 4 can be applied). For example, D can be affected by dehydration, varying degrees of annealing at high temperatures, and strain induced during rapid

Figure 6 Temperature dependence of thermal diffusivity and conductivity for type I fused quartz (SiO₂ glass: data from [10] and citations therein). Lower temperature results scaled to match LFA results. Quartz crystal polymorphs (labeled α and β) are shown for comparison.

Figure 7 Thermal diffusivity as a function of temperature for moldavite and anorthite, both glasses and melts [11 and citations therein]. Molten anorthite crystallized above 1330 K, causing D to sharply increase.

cooling from high temperature. The variation among identical samples can be attributed in some cases to small but variable amounts of bubbles and crystallites in the samples, as well as to residual strain.

For glasses, k initially has a variation opposite to that of D , increasing steadily from low temperature (Figure 4),

Figure 8 Thermal conductivity of obsidians with different crystal contents. Data are calculated from the product of thermal diffusivity (measured at T), heat capacity (calculated at T), and density at room temperature (thermal expansion introducing a negligible uncertainty). Error bars of $\pm 2\%$ are plotted on symbols for two samples: NCr is a crystal-free remelt, and SCE is the most crystalline sample (2 vol % crystals). Curves are calculated from a least squares fit to the data [16]. Data on remelted, crystal-free glass are provided in the tables.

but, like D (Figure 6), becoming nearly constant at high temperature (Figure 8). As such, k differs much for glasses compared with most crystals for which k first increases at cryogenic temperatures, reaches a maximum near room temperature, and then decreases. Because D varies similarly for glasses and crystals (Figure 6), the difference between both kinds of phases for k necessarily results from the relative magnitudes and changes in C_p and D with temperature. For glasses, C_p overwhelms D , so the temperature response of k largely follows that of C_p . For crystals, the strong increase in C_p initially dominates at low temperature, whereas the continuing decrease in D prevails at high temperature, so the complex temperature response of k is due to the interplay of D and C_p . This difference has been the focus of both experimental and theoretical research, in which glasses are treated differently than crystals, e.g. [1].

Low-temperature methods involve little radiative transfer, and they can be corrected for contact resistance losses through comparison with LFA data (Figure 4). For silica, a small correction term of a few percent was used to merge data on D and k from a few K to the liquidus temperature [10].

For glasses, fits may be made to the LFA data with expressions of the form

$$D = FT^{-G} + HT, \quad (15)$$

(Figure 7). All data obtained so far are well described by Eq. (15) [18]. From phonon scattering models, the exponent G is expected to be unity for well-ordered crystals. However, for highly disordered feldspar crystals, similar fits give a small value for G of about 0.5. The transport properties of these materials are similar to those of glasses (see Pohl [1] for discussion), as borne out by the G values of 0.15–0.5 that we found for our glasses (Table 2), which are by definition highly disordered.

4.2 Effects of the Glass Transition and Melt Properties

All LFA studies of glasses have found that D decreases across the glass transition (Figures 5–7). These measurements probe relaxed melts, starting at temperatures corresponding to a viscosity of $\sim 2 \times 10^8$ Pa·s. One can interpret this value by considering the relaxation time-scale (τ_r) calculated from the Maxwell relationship ($\eta = G_\infty \tau_r$). Because the shear modulus at infinite frequency G_∞ is about 10 GPa, τ_r is ~ 1 to 10 ms, a value that is commensurate with the duration of the laser pulse in LFA. Consequently the glass transition in LFA heat-transfer experiments ($T_{g,LFA}$) occurs at a substantially higher temperature and lower viscosity than in viscometry experiments ($T_{g,12}$) simply because of the short time-scale over which the laser probes the sample. Above $T_{g,12}$, but below $T_{g,LFA}$, a viscous liquid appears frozen (glassy) on the short timescale of the laser pulse, although it can still flow over the longer (minutes to hours) timescale of a viscosity measurement. Although the state immediately above the glass transition is (metastable) supercooled liquid, the thermal diffusivity measured above $T_{g,LFA}$ represents that of structurally relaxed liquid up to and including superliquidus conditions and is denoted D_{melt} . For brevity, we refer to this state simply as melt or liquid.

Upon crossing the glass transition, D decreases substantially, to ~ 0.35 mm²/s for Ca-rich melts, but only weakly, to ~ 0.52 mm²/s for Al-rich melts (Figure 7; Table 2). The magnitude of the decrease in D at $T_{g,12}$ correlates with the melt fragility and also with the configurational heat capacity [11]. The close correspondence between C_p and D^{-1} is consistent with greater configurational changes in the melts producing greater disruption of lattice heat transfer [10, 11]. Increased disorder causes D to decrease because disorder is associated with a greater number of vibrational states, leading to an increase in the number of types of phonon collisions, and because enhanced collisions provide a shorter mean free path.

All LFA measurements indicate that melts have low D (Figures 3, 5–7, and 9), which depends on composition. For example, more polymerized aluminosilicates have higher D than less polymerized soda-lime glasses or slags [5, 11, 15].

Figure 9 Thermal conductivity of molten slags (calcium aluminum silicates with varying proportions: labels are in wt %). Heavy solid line: LFA data on anorthite above the liquidus [11]. Symbols: examples of the many slags studied by Kang and Morita [15]. Lines are least squares linear fits. We do not provide details on compositions or fits in the tables because the T -dependence does not agree with LFA or thermoreflectance data (see text).

Data collected with contact methods on calcium aluminosilicate slags show a strong decrease in k with increasing temperature (Figure 9). This contrasts with the results of LFA or thermoreflectance studies, which suggest that D of the melt slightly increases with temperature (Figure 3; Table 2). The calculated k values of the melt (Table 3) consequently show weak changes (which themselves depend on the temperature dependence of heat capacity). The trend in D with T of the slags [15] cannot be due to radiative transfer, because this would artificially elevate k . This comparison points to the difficulty of accurately measuring thermal transport for melts and slags [5] and emphasizes the need for benchmarking the various techniques, with identical samples, especially at high temperatures.

4.3 Effects of Composition and Crystallinity and Correlation with Fragility

Mass and heat transport properties are linked to chemical composition such that a dichotomy exists between the properties of mafic melts (which have low degrees of polymerization and are referred to as basic in the slag literature) and of felsic (highly polymerized) melts, the latter having higher viscosity and higher thermal diffusivity. Strong correlations have been found with Ca and Al

contents, whereby increasing concentrations of either cation lowers D [11] (see Table 2). However, high Ca contents result in low D for glasses and melts, whether or not Al is present. Thermal conductivity of Ca–Al–Si molten slags varies in the same manner [15] (see also Figure 9). Similar responses exist for k and D because heat capacity and density of melts are approximately constant at high T and vary little over the small temperature intervals accessed in the heat-transfer experiments (spreads of 200–300 K exist in those of Kang and Morita [15]). These findings are consistent with the network-modifying role of Ca, which leads to an increase of NBO/ T as Ca increases [7, 11]. Calcium is also known to increase thermal expansivity of melts (Chapter 3.5), and D is connected with thermal expansivity for SiO_2 glasses [10]. For slags, k depends on NBO/ T [5].

Few data exist on the effect of Fe substitution on D values, although small amounts apparently decrease D for glasses at low temperature, which is consistent with Fe being a network modifier. However, at high temperature, iron cations act in a different way: in their presence, D of both glass and liquid increases as temperature increases, as discussed further in Section 4.4.

Interestingly, k for glasses at 298 K can be predicted from partial molar sums of oxides [7]. This situation is attributable to the slight compositional dependence of D in glasses (Table 2), whereas C_p is well predicted from oxide sums (Chapter 3.6).

Configurational changes in the liquid upon heating are reflected in the melt fragility, which describes how steeply viscosity decreases above the glass transition (Chapter 4.1). The nominal degree of polymerization (NBO/ T) is less useful as a discriminant because feldspathic melts are nominally fully polymerized, yet they show a range in D depending on whether they are Ca, Na, or K rich. Generally, both D of glass and melt decrease as fragility increases (Figure 10). Other factors must also be important, as indicated by the observed spread in values. Nevertheless, this well-defined trend substantiates that a link exists between heat and mass transport properties.

Density reflects both structural and chemical characteristics. The overall decrease in D_{melt} as melt density increases (Figure 11) is connected with the presence of heavy cations. Cations such as Ca and Fe have low-energy vibrations that are less effective at transporting heat. This effect is seen with glasses and crystals as well. Silicic melts typically have high D and η and low fragility and ρ , linking heat and mass transport. Similarly, k of glass has been linearly correlated with density for simple compositional series [7]. However, the linear dependence of k on ρ for glass does not hold over a broad compositional range [7]. Trends in k ascertained from direct measurements are more difficult to establish because of experimental
